The manual testing of muscles or muscle strength is not new, and was used in the late 1940s to evaluate muscle function and strength and to assess the extent of an injury. Applied kinesiology measures whether a muscle is stuck in the "on" position, acting like a tense muscle spasm, or is stuck "off," appearing weak or flaccid. It is called manual testing because it is done without instruments, using only the kinesiologist's fingertip pressure. During the first and longest appointment, which lasts about an hour, the kinesiologist conducts a complete consultation, asking about the patient's history and background. During the **physical examination**, patients sit or lie down, then the kinesiologist holds the patient's leg or arm to isolate a particular muscle. The practitioner then touches a point on the body which he believes is related to that muscle, and, with quick, gentle, and painless pressure, pushes down on the limb. Patients are asked to resist this pressure, and, if they cannot, an imbalance is suspected in the related organ, gland, or body part. This diagnostic technique uses muscles to find the cause of a problem, and is based on **traditional Chinese medicine** and its idea that the body has common energy meridians, or channels, for both organs and muscles. Kinesiologists also claim that they are able to locate muscle weaknesses that stem from a variety of causes such as **allergies**, mineral and vitamin deficiencies, as well as from problems with the lymph system. Once the exact cause is determined, the kinesiologist uses his fingertips to work the appropriate corresponding acupressure points in order to rebalance the flow of energy and restore health. Often he will recommend a complementary program of **nutrition** therapy.

KEY TERMS

Acupressure—A form of acupuncture in which certain points of the body are pressed with the fingers and hands to release energy blocks.

Alleviate—To make something easier to be endured.

Complementary—Something that serves to fill out or complete something else.

Deficiency—A shortage of something necessary for health.

Diagnostic—The art or act of identifying a disease from its signs and symptoms.

Flaccid—Flabby, limp, weak.

Meridian—In traditional Chinese medicine, the channels which run beneath the skin through which the body's energy flows.

Spasm—An involuntary, sudden, violent contraction of a muscle or a group of muscles.

Results

If applied kinesiology does what it claims, patients should expect muscle testing to discover the cause of their physical complaint and to be told how to correct it.

Risks

There are no major risks associated with this gentle, noninvasive therapy. It is generally safe for people of all ages and has no side effects.

Klebsiella

Definition

Klebsiella is a genus of nonmotile rod-shaped gram-negative bacteria belong to the Enterobacteriaceae family. Named for the nineteenth-century German microbiologist Edwin Klebs (1834–1913), the organisms are enclosed in a polysaccharide capsule that protects them against many defenses of a host's immune system. The capsule also contributes to the bacterium's drug resistance. Under a microscope, *Klebsiella* look like straight rods with slightly pointed or rounded ends; they may appear as single organisms, in pairs, or in long chains. The five species of *Klebsiella* are found almost everywhere in the natural world, in water, soil, and plants as well as animals and humans. They thrive best at temperatures between 95°F and 98.6°F (35°C to 37°C), which is close to the temperature of the human body.

Description

Klebsiella are normally found in the human mouth, nose, and digestive tract, where they ordinarily do not cause disease. In immunocompromised persons, however, the bacteria become opportunistic pathogens, causing illnesses ranging from urinary tract infections (UTIs) to soft tissue infections and **diarrhea**. Most illnesses in humans are caused by *Klebsiella pneumoniae*, followed by *Klebsiella oxytoca* and *Klebsiella granulomatis*. These bacteria have become increasingly important to disease specialists in recent years because of their association with nosocomial, or hospital-acquired, infections. **Hospital-acquired infections** (HAIs) include **pneumonia**, infections of the bloodstream, wound infections, and bacterial **meningitis**; most are associated with surgical incisions or the use of such invasive medical devices as catheters, feeding tubes, esophageal intubation, and respirators.

In addition to their association with HAIs, *Klebsiella* infections have caused great concern in recent years because the bacterium has developed resistance to carbapenem **antibiotics**, considered drugs of last resort against antibiotic-resistant bacteria. *Klebsiella* is one of several Enterobacteriaceae genera that has become resistant to carbapenem, defining them as carbapenem-resistant Enterobacteriaceae or CRE. *Klebsiella* becomes immune to carbapenem antibiotics by producing an enzyme called carbapenemase, which breaks the structure of the antibiotic. *Klebsiella* that produce carbapenemase are known as KPC-producing bacteria.

CRE is now considered a "superbug," with a higher fatality rate than either methicillin-resistant *Staphylococcus aureus* (MRSA) or *Clostridium difficile*. CRE appear to have developed in the United States; according to the Centers for Disease Control and Prevention (CDC), the first case was reported in a hospital in North Carolina in 2001. As of 2014, 41 states have reported CRE infections, and the drug-resistant strains have been found in Canada, Israel, Australia, Thailand, and 19 other countries. The CDC issues a report in March 2013 stating that CRE infections kill up to 50% of hospital patients infected with the bacteria.

Risk factors

Risk factors for carbapenem-resistant *Klebsiella*

- Age: young children and the elderly are at highest risk; most infections in newborns and infants are caused by *K. oxytoca*.
- Sex: women are at higher risk than men except in the older age groups.
- Inpatient treatment in an acute care facility (particularly in an ICU) or long-term care facility; the risk increases in proportion to the length of the patient's stay.
- Previous treatment with beta-lactam or fluoroquinolone antibiotics.
- Having an organ transplant or being placed on a mechanical ventilator.

- Having diabetes.
- Living in a country where antibiotics are available as over-the-counter medications, as in Thailand or Egypt.
- Having cancer, HIV infection, or any other disorder that weakens the immune system.
- History of alcoholism; about 66% of inpatients in U.S. hospitals with *Klebsiella* infections are alcoholics.
- History of asthma, emphysema, or other lung disease.

Demographics

About 2 million patients in the United States each year develop hospital-acquired infections (HAIs); about 8% of these infections are caused by *Klebsiella* bacteria. *Klebsiella* species are among the top 8 disease organisms found in hospitals in North America. They may affect any part of the body, but are most likely to be associated with UTIs and lung infections in Canada and the United States.

Infections caused by*K. pneumoniae* are common worldwide, while those caused by *K. granulomatis* are more common outside North America, in South Africa, Zimbabwe, parts of Australia, southeast Asia, South America, and the Caribbean.

Causes and symptoms

Klebsiella infections are caused when the bacteria enter hosts with weakened immune systems. The polysaccharide capsule surrounding *Klebsiella* protects the organisms from engulfment by phagocytes and from factors in the blood serum that ordinarily kill bacteria. In addition, *Klebsiella* also secrete components on their cell surfaces known as adhesins, which enable them to cling to the surfaces of host cells.

Lung infections caused by *Klebsiella* usually develop after the patient has aspirated bacteria from the mouth and throat into the lower respiratory tract. In the lungs, *Klebsiella* cause such destructive changes as inflammation, hemorrhage, and the death (**necrosis**) of lung tissue, leading to a thick, bloody discharge known as currant-jelly sputum. Symptoms include the acute onset of high **fever**, flu-like symptoms, chills, and coughing that produces the characteristic bloody sputum.

Urinary tract infections caused by *Klebsiella* have the same symptoms as UTIs produced by other bacteria: painful urination (dysuria), urinary urgency, lower back **pain**, and pain or cramping over the pubic bone.

Infection of **wounds**, surgical incisions, or contamination of urinary catheters and other invasive devices may lead to *Klebsiella* gaining admission to the bloodstream, a condition known as **bacteremia**. Bacteremia can progress to **sepsis** and **septic shock**.

Diagnosis

Diagnosis begins with the doctor's taking a careful history and noting the presence of risk factors associated with *Klebsiella*, particularly long-term hospitalization, the use of catheters, respirators, or other invasive devices, a previous recent course of antibiotics, and any indications that the patient has a weakened immune system.

To distinguish infection with *Klebsiella* from other bacterial infections, the doctor will order a culture using material taken from a sputum sample or swabs obtained from wound sites, catheters, intravenous lines, or respiratory equipment. *Klebsiella* species can be identified under the microscope after Gram staining. They can also be identified by using the Voges-Proskauer and methyl red tests, which test bacteria for the digestion of glucose and for acidity. The test solutions will turn a cherry red color if *Klebsiella* are present.

Treatment

Treatment depends on whether the particular strain of *Klebsiella* is antibiotic-resistant. Antibiotic therapy is usually empiric, which means that the doctor begins treatment with antibiotics before the diagnosis of the specific strain of *Klebsiella* is confirmed. The antibiotics given may include third-generation **cephalosporins** (cefotaxime and ceftriaxone), carbapenems, **aminoglycosides**, and quinolones.

If the *Klebsiella* is determined to be a KPC-producing bacterium, it will be resistant to carbapenem antibiotics as well as to **penicillins**, cephalosporins, **fluoroquinolones**, and aminoglycosides. As of 2014, the only drugs that are effective in treating resistant *Klebsiella* infections are colistin, tigecycline, and intravenous fosfomycin. Antibiotic therapy lasts for 14 to 21 days, depending on the severity of the infection. Patients must finish the full course of antibiotic treatment even if their symptoms improve before then.

Surgery may be required in severe cases of *Klebsiella* pneumonia, in order to remove abscesses in the lungs or gangrenous tissue.

Prognosis

The prognosis of pneumonia caused by *Klebsiella* is guarded; if the organism is antibiotic-resistant,

KEY TERMS

Bacteremia—The presence of bacteria in the bloodstream.

Carbapenem-resistant Enterobacteriaceae (CRE)—A group of bacteria in the Enterobacteriaceae family that are increasingly resistant to carbapenem antibiotics. *Klebsiella* bacteria are one type of CRE.

Carbapenemase—An enzyme produced by CRE that makes the bacteria resistant to carbapenems by breaking the structure of the antibiotic.

Carbapenems—A class of beta-lactam antibiotics with a broad spectrum of antibacterial activity. They are often considered antibiotics of last resort.

Empiric therapy—Therapy that begins before the diagnosis is firmly established. The term is most often used to refer to antibiotic treatment started before the bacterium causing the disease is identified.

Gram-negative—A term that refers to bacteria that do not retain the crystal violet stain used in the Gram method of classifying bacteria. The name of the method comes from its inventor, Hans Christian Gram (1853–1938), a Danish bacteriologist.

Nosocomial—Pertaining to or acquired in a hospital.

Opportunistic infection—An infection caused by a disease organism that does not cause illness in a healthy person but does cause disease in a person with a weakened immune system.

Phagocyte—A specialized white blood cell that protects the body by ingesting bacteria, foreign particles, and dead or dying cells.

Polysaccharide—A complex carbohydrate that consists of long chains of monosaccharides bound together.

Sepsis—A serious medical condition characterized by an inflammatory response of the entire body and the presence of a suspected or known infection.

Septic shock—Severe sepsis with persistent low blood pressure despite fluid resuscitation and resulting inadequate tissue perfusion. The mortality rate of septic shock is 25–50%.

mortality approaches in 50% in alcoholics and patients with bacteremia, mortality is close to 100%. Bacteremia progressing to septic **shock** has a mortality rate of 25–50%.

UTIs caused by *Klebsiella* usually have a good prognosis.

Prevention

Vaccine

Researchers have been working on a *Klebsiella* vaccine since the 1980s. In 2013, a team of vaccine specialists in Austria announced the identification of several protein antigens that are promising candidates for a vaccine against *K. pneumoniae*. It will take several years, however, to develop a candidate vaccine and test it in clinical trials. Thus there is no vaccine effective against *Klebsiella* as of 2014.

Hygienic measures

Health care professionals are required to follow the CDC's 2007 guideline to protect patients from the spread of *Klebsiella*. The guideline specifies the following precautions:

- Healthcare personnel are required to wear personal protective equipment (PPE) when caring for patients with any antibiotic-resistant infection, including *Klebsiella*. PPE includes isolation gowns, gloves, masks, goggles, and face shields.
- The patient's room is to be cleaned and disinfected regularly, including surfaces most likely to be contaminated by *Klebsiella*: bed rails, bedside tables, toilets or bedpans, doorknobs, sinks, and the surfaces of equipment close to the patient's bed.
- Medical equipment and devices must be carefully cleaned of blood, tissue, and all other organic material prior to high-level disinfection and sterilization.
- Visitors are screened before being allowed to see the patient, and are expected to observe careful hand hygiene.

Patients in hospitals and long-term care facilities should protect themselves by cleaning their hands often, especially:

- before eating food or preparing it
- before touching the eyes, mouth, or nose
- before and after changing bandages or wound dressings
- after coughing, sneezing, or blowing the nose
- after using the bathroom, as *Klebsiella* can be found in human feces

- after touching any surfaces on hospital furniture or such items as the telephone or television remore control

The patient's family members should also practice careful hand hygiene to protect the patient; however, healthy family members are at low risk of becoming infected themselves.

Klinefelter syndrome

Definition

Klinefelter syndrome is a chromosomal disorder that affects only males. People with this condition are born with at least one extra X chromosome. The syndrome was first identified and described in 1942 by Harry Fitch Klinefelter, Jr., an American physician.

Description

Klinefelter syndrome is a condition in which one or more extra X chromosomes are present in a male. Boys with this condition appear normal at birth. They enter **puberty** normally, but by mid puberty have low levels of testosterone causing small testicles and the inability to make sperm. Affected males may also have learning disabilities and behavior problems such as **shyness** and immaturity, and an increased risk for certain other health problems.

Klinefelter syndrome is one of the most common chromosomal abnormalities. About 1 in every 500 to 800 males is born with this disorder; approximately 3000 affected boys are born each year in the United States. About 3% of the infertile male population have Klinefelter syndrome. The condition appears to affect all racial and ethnic groups equally.

WWW.BOOKBAZ.IR

Causes and symptoms

Chromosomes are found in the cells in the body. Chromosomes contain genes, structures that tell the body how to grow and develop. Chromosomes are responsible for passing on hereditary traits from parents to child. Chromosomes also determine whether the child will be male or female. Normally, a person has a total of 46 chromosomes in each cell, two of which are responsible for determining that individual's sex. These two sex chromosomes are called X and Y. The combination of these two types of chromosomes determines the sex of a child. Females have two X chromosomes (the XX combination); males have one X and one Y chromosome (the XY combination).

In Klinefelter syndrome, a problem very early in development results in an abnormal number of chromosomes. About 60% of embryos with Klinefelter syndrome do not survive the fetal period. Most commonly, a male with Klinefelter syndrome will be born with 47 chromosomes in each cell, rather than the normal number of 46. The extra chromosome is an X chromosome. This means that rather than having the normal XY combination, the male has an XXY combination. Because people with Klinefelter syndrome have a Y chromosome, they are all male.

Approximately 1/3 of all males with Klinefelter syndrome have other chromosomal abnormalities involving an extra X chromosome. Mosaic Klinefelter syndrome occurs when some of the cells in the body have an extra X chromosome and the others have normal male chromosomes. These males can have the same or milder symptoms than non-mosaic Klinefelter syndrome. Males with more than one additional extra X chromosome, such as 48,XXXY, are usually more severely affected than males with 47,XXY.

Klinefelter syndrome is not considered an inherited condition. The risk of Klinefelter syndrome reoccurring in another **pregnancy** is not increased above the general population risk.

The symptoms of Klinefelter syndrome are variable and not every affected person will have all of the features of the condition. Males with Klinefelter syndrome appear normal at birth and have normal male genitalia. From childhood, males with Klinefelter syndrome are taller than average with long limbs. Approximately 20–50% have a mild intention tremor, an uncontrolled shaking. Many males with Klinefelter syndrome have poor upper body strength and can be clumsy. Klinefelter syndrome does not cause homosexuality. Approximately 1/3 of males with Klinefelter syndrome have **gynecomastia** or breast growth, some requiring **breast reduction** surgery.

Most boys enter puberty normally, though some can be delayed. The Leydig cells in the testicles usually produce testosterone. With Klinefelter syndrome, the Leydig cells fail to work properly causing the testosterone production to slow. By mid-puberty, testosterone production is decreased to approximately half of normal. This can lead to decreased facial and pubic hair growth. The decreased testosterone also causes an increase in two other hormones, follicle stimulating hormone (FSH) and luteinizing hormone (LH). Normally, FSH and LH help the immature sperm cells grow and develop. In Klinefelter syndrome, there are few or no sperm cells. The increased amount of FSH and LH causes hyalinization and fibrosis, the growth of excess fibrous tissue, in the seminiferous tubules, where the sperm are normally located. As a result, the testicles appear smaller and firmer than normal. With rare exception, men with Klinefelter syndrome are infertile because they can not make sperm.

While it was once believed that all boys with Klinefelter syndrome are mentally retarded, doctors now know that the disorder can exist without retardation. However, children with Klinefelter syndrome frequently have difficulty with language, including learning to speak, read, and write. Approximately 50% of males with Klinefelter syndrome are dyslexic.

Some people with Klinefelter syndrome have difficulty with social skills and tend to be more shy, anxious, or immature than their peers. They can also have poor judgment and do not handle stressful situations well. As a result, they often do not feel comfortable in large social gatherings. Some people with Klinefelter syndrome can also have **anxiety**, nervousness and/or depression.

The greater the number of X chromosomes present, the greater the disability; each extra X chromosome lowers the child's IQ by about 15 points. Boys with several extra X-chromosomes have distinctive facial features, more severe retardation, deformities of bony structures, and even more disordered development of male features.

Diagnosis

Diagnosis of Klinefelter syndrome is made by examining chromosomes for evidence of more than one X chromosome present in a male. This can be done in pregnancy with prenatal testing such as a **chorionic villus sampling** or **amniocentesis**. Chorionic villus sampling is a procedure done early in pregnancy (approximately 10–12 weeks) to obtain a small sample of the placenta for testing. An amniocentesis is done further along in pregnancy (from

KEY TERMS

Chromosome—A microscopic thread-like structure found within each cell of the body and consists of a complex of proteins and DNA. Humans have 46 chromosomes arranged into 23 pairs. Changes in either the total number of chromosomes or their shape and size (structure) may lead to physical or mental abnormalities.

Gonadotrophin—Hormones that stimulate the ovary and testicles.

Gynecomastia—Excessive growth of breast tissue in males.

Leydig cells—Cells that make up the endocrine tissue of the testis and produce testosterone. They are named for Franz von Leydig (1821–1908), the German professor of anatomy who first identified them.

Testosterone—Hormone produced in the testicles that is involved in male secondary sex characteristics.

approximately 16–18 weeks) to obtain a sample of fluid surrounding the baby for testing. Both procedures have a risk of **miscarriage**. Usually these procedures are done for a reason other than diagnosing Klinefelter syndrome. For example, a prenatal diagnostic procedure may be done on an older woman to determine if her baby has **Down syndrome**. If the diagnosis of Klinefelter syndrome is suspected in a young boy or adult male, chromosome testing can also be on a small blood or skin sample after birth.

Many men with Klinefelter syndrome go through life without being diagnosed. The two most common complaints leading to diagnosis of the condition are gynecomastia and **infertility**.

Treatment

There is no treatment available to change a person's chromosomal makeup. Children with Klinefelter syndrome may benefit from **speech therapy** for speech problems or other educational interventions for learning disabilities. Testosterone injections started around the time of puberty may help to produce more normal development including more muscle mass, hair growth and increased sex drive. Testosterone supplementation will not increase testicular size, decrease breast growth or correct infertility. Psychiatric consultation may be helpful when the boy reaches adolescence.

Some doctors recommend **mastectomy** as a surgical treatment for gynecomastia, on the grounds that the enlarged breasts are often socially stressful for affected males and significantly increase their risk of **breast cancer**.

Prognosis

While many men with Klinefelter syndrome go on to live normal lives, nearly 100% of these men will be sterile (unable to produce a child). However, a few men with Klinefelter syndrome have been reported who have fathered a child through the use of assisted fertility services.

Males with Klinefelter syndrome have an increased risk of several systemic conditions, including **epilepsy**, **osteoporosis**, such **autoimmune disorders** as lupus and arthritis, diabetes, and breast and **germ cell tumors**. One Danish study reported in 2004 that men with Klinefelter's syndrome have a slightly shortened life span, dying about 2.1 years earlier than men without the syndrome.

Knee injuries

Definition

The knee joint consists of bone, ligaments, cartilage, and fluid. It moves with the help of surrounding muscles and tendons. When any of these structures is degraded, the knee can become injured. According to the Mayo Clinic, nearly one out of three Americans older than 45 years of age have some type of knee **pain**. Whether it is a minor or major problem, it usually involves a certain amount of pain and a degree of difficulty in walking.

The five most common knee problems are arthritis, tendonitis, **bruises**, cartilage tears, and damaged ligaments, with arthritis being the most common problem of the bones of the knee. The ligaments and tendons of the knee can also become injured. Damage to the anterior cruciate ligament (ACL) is a common problem of knee ligaments and tendons. Knee injuries can be caused by accidents, impacts and other such traumas, sudden or awkward movements (misalignments), and gradual wear and tear of the knee joint (degeneration).

Most injuries of the knee are minor and are usually treated at home with rest and ice packs. Serious injuries necessitate treatments by physicians and **rehabilitation** experts. Often, various types of surgeries are needed to correct the worst knee injuries such as a ruptured ligament or tendon.

Demographics

Because the knee joint is both vulnerable and used extensively in many activities, it is prone to injuries in all peoples young and old. The American Academy of Orthopaedic Surgeons (AAOS) estimates that approximately nine million American adults are diagnosed with knee **osteoarthritis** each year. Osteoarthritis of the knee is deterioration (degradation) of the knee joint. Over half of all people with knee osteoarthritis were over the age of 65 years. The AAOS states that knee osteoarthritis is a leading cause of disability in the United States. In some sports including football, skiing, gymnastics, and racket sports, injury rates to avid practitioners can be nearly 50%, and knee injuries are the most common reason patients visit orthopedic doctors. An estimated one in five runners gets a knee injury at some point in their lives. The majority of knee injuries, however, are minor and do not require intensive treatment.

Description

The knee, the largest joint in the body, connects the thighbone (femur) to the lower leg (tibia). It is a complex and efficient joint consisting of ligaments, cartilage, and the bone of the kneecap (patella). All of these parts can be injured. Inside the knee joint is synovial fluid that protects and lubricates the parts, which may increase as the result of an injury, causing swelling. The bursa are sacs in the knee that contain synovial fluid and provide cushioning and lubrication.

Four ligaments comprise the knee joint. The medial collateral ligament (MCL) runs along the inside of the knee, while the lateral collateral ligament (LCL) is on the outside of the knee. The cruciate ligaments cross inside the knee. The anterior cruciate ligament (ACL) is deep inside the knee and limits rotation of the joint. The posterior cruciate ligament (PCL) is also inside the knee and limits the backward movement of the joint. Ligaments in the knee can be partially or completely torn, depending on the extent of the injury.

The minisci cartilage are two thin, oval–shaped tissues that act as cushions between the ends of the leg bones. The medial miniscus is the cartilage closest to the other leg while the lateral miniscus is nearer the outside of the knee. Injuries to the minisci include tears from injuries and impact and degenerative wearing away of the structure. The minisci can be partially or completely torn during injury.

The bones around the knee, including the kneecap, can be broken, fractured, or chipped. The patellar tendon connects the kneecap to the shinbone, while the quadriceps tendon connects the quadriceps muscle

to the patella. The patellar tendon can be torn or can develop injury and pain from degeneration. It can also be fully dislocated or partially dislocated (called subluxation). The tendons in the knee may develop pain and inflammation known as tendonitis.

The bones of the knee joint are covered with tissue known as articular cartilage. This cartilage can be injured or fractured, and can also develop a degenerative condition called chondromalacia. Osteoarthritis is the condition associated with the wearing down of this cartilage.

There are many risks that increase one's chance of having a knee injury. These risks include:

- Excessive weight, being obese, because of the additional weight being carried in part by the knees.
- Sports and activities that are considered high risk for knee injuries, such as basketball, racquetball, downhill skiing, and tennis.
- Overuse, repeated activities can lead to fatigue in the muscles around the joints and contribute to tissue damage.
- Neuromuscular abnormalities, such as different lengths for legs and misaligned knees, can increase the likelihood of knee injuries.
- Muscle inflexibility and weakness provides less support for the knee and adds to more stress placed upon the knees.
- Previous injuries to the knee make is more likely that future knee injuries will occur.
- Gender increases the likelihood of certain types of knee problems; that is, males are more likely to have some knee problems (such as a dislocated kneecap), while females are more likely to have others (such as Osgood–Schlatter disease).
- Age increases the likelihood of more knee problems.

Causes and symptoms

Knee injuries are commonly caused by the following: impact (such as from an accident, landing after a fall, and a blow from an object), repeated stress/overuse, sudden motion (excessive turning, pivoting, or stopping), rapidly growing bones, and age-related degeneration.

There are many specific causes of knee injuries. Arthritis may develop from an auto-immune disorder, known as **rheumatoid arthritis**, or may be caused by the gradual wear and tear of the joint, known as osteoarthritis. Symptoms of arthritis in the knee include pain ranging from dull aches to severe pain, and may be accompanied by swelling and range of movement loss. Arthritic symptoms may tend to be worst in the morning and decrease throughout the day as the knee is used. Arthritis can be caused by lupus, **Lyme disease**, and other infections.

Hyperextended knee can occur when the knee is extended beyond its normal range. When this happens the knee bends back on itself, which usually causes minor damage, along with pain and swelling. However, hyperextended knee can also cause a partial or complete tear in a ligament, which produces more problems. Then the patella, the bone that covers the front of the knee, is dislodged from its normal position, so a dislocated kneecap can occur. The kneecap will look obviously out of place, and it can even be moved from side to side with ease. Symptoms of a hyperextended knee include swelling, intense pain, problems straightening the knee, and difficulty walking.

Cartilage injuries may include chondromalacia, with symptoms including dull pain at any time and more intense pain while climbing stairs. Damage to the minisci cartilage often occurs from sudden twists, forceful plants, and awkward movements. (The meniscus is a C-shaped piece of cartilage that curves inside of the knee joint.) A torn cartilage may make a popping sound, and may be accompanied by mild to severe pain, particularly while straightening the leg. Swelling, stiffening, and loss of movement are also symptoms of cartilage tears, as are clicking sounds and friction in the knee during movement. A knee suffering from a cartilage injury may become completely immobile.

Ligament injuries, which produces immediate pain when it occurs, may cause dull or severe pain, swelling, loss of the range of movement of the joint, and loss of the stability and strength of the knee. Ligament injuries typically occur from strong blows and forces applied to the knee. Injuries to the MCL are the most common, often caused by impact to the side of the knee joint. Of the cruciate ligaments, the PCL is less commonly injured than the ACL. Typically, forceful blows to the knee, such as during car accidents, injure the PCL, while the ACL can be injured by impacts and by sudden twists. Torn ligaments may be accompanied by a popping sound indicating the rupture, and may not always cause pain, so that some of them go unnoticed. Torn ligaments may weaken the knee and cause buckling or folding under weight.

Tendon injuries range from tendonitis to torn tendons. Symptoms of tendonitis include pain (which worsens when movement occurs such as running or climbing), irritation, inflammation, inability to completely extend or straighten the knee, and swelling (especially in the front of the knee or just below the kneecap), while ruptured tendons can cause more intense pain, swelling, and loss of movement.

WWW.BOOKBAZ.IR

Osgood–Shlatter disease is a condition common in young boys and girls who play running and jumping sports. Symptoms include swelling, tenderness of the tibial tuberosity located below the kneecap, and inflammation of the patellar tendon and pain in the front of the knee during and after strenuous activity.

Iliotibial band syndrome is common in running and other repetitive sports, characterized by a sharp, burning pain at the outer side of the knee caused by **stress** on the band of tendons there. Sometimes this condition causes a snapping sensation when the knee is straightened. Long-distance runners are especially susceptible to illiotibial band syndrome. The pain usually goes away when at rest after running but returns when climbing occurs. Swelling usually does not occur with this problem and normal range of motion within the knee is usually present.

Bursitis is a problem caused by inflammation in the bursa, or the small fluid sacs that cushion the outside of the knee joint. Symptoms of bursitis include redness, swelling, constant pain, stiffness or aching while walking, and added pain when climbing. Infection may also occur within the bursae, which can cause **fever**, and additional pain and swelling.

Diagnosis

Depending on the severity of the condition, family physicians or orthopedic physicians who specialize in the knee joint may be consulted. A complete **physical examination** will be performed, along with a comprehensive review of past medical records. If arthritis is suspected, a rheumatologist may be consulted. The diagnostic process includes taking a complete patient history with details of the pain and the circumstances of the injury. During a physical exam, the doctor will specifically include several manual techniques of moving the knee joint and legs in various positions to help determine the type of injury. An experienced practitioner can often make an accurate diagnosis of injuries by performing a sequence of manual diagnostic tests.

Laboratory tests may be ordered to further or clarify the diagnosis. X rays can show damage to the bones as well as the narrowing of the knee space that may imply cartilage problems. For more in-depth diagnosis, a computerized axial tomographic (CAT) scan is an x-ray technique that can provide three-dimensional views of the bones in the knee. A **magnetic resonance imaging** (MRI) scan gives a computerized portrait of the interior of the knee, and may show damage to the ligaments and cartilage. **Arthroscopy** is a form of minor surgery in which a tiny camera is inserted into the knee, giving a very accurate view of the joint. Radionuclide scanning (bone scans) use radioactive material injected into the bloodstream to monitor the blood flow in particular areas. If infection or rheumatoid arthritis is suspected, a physician may order blood tests for diagnosis. Biopsies, in which pieces of tissue are laboratory tested, may also be used for diagnosis.

Treatment

When a person suspects a knee injury, the first treatment recommended by the Mayo Clinic is a process called P.R.I.C.E., which stands for protection, rest, ice, compression, and elevation. First, the person should "protect" the knee from further motion by using a wrap that immobilizes the knee and/or crutches or braces if necessary. Then, cease the activity that caused the injury and immediately "rest" and immobilize the joint. "Ice" may be applied to reduce pain and swelling, and "compression", such as wraps and braces, may be used to immobilize the knee. "Elevating" the leg is also helpful in reducing swelling and aiding circulation. Immediate care will prevent the worsening of the injury.

Generally, pain relievers such as nonsteroidal anti–inflammatory drugs (NSAIDs) can be used. They include **aspirin**, ibuprofen (such as Advil), and naproxen (such as Aleve). **Physical therapy** may also be necessary so that the knee regains is normal movement.

Treatment options for knee injuries can range from rest and light activity, to physical therapy, to surgery. Most knee injuries are treated with proper rest, **exercise**, and strengthening programs recommended by physicians. For injuries that require surgery or deeper diagnosis, arthroscopy is the least invasive technique and involves a short recovery time. Arthroscopy is commonly used to repair cartilage and partially torn ligaments. For severe knee injuries, **reconstructive surgery** or open knee surgery may be required. Full knee replacements may also be performed for severely damaged knees. After surgery, physical therapy programs for rehabilitation are recommended. Treatment for osteoarthritis includes over-the-counter painkillers, exercise, and weight reduction. For rheumatoid arthritis, more powerful prescription medications, such as **steroids** and stronger painkillers, and intensive physical therapy may be ordered. Knee injuries associated with infection may require **antibiotics**.

Alternatives

Alternative therapies for knee injuries focus on supporting the body's ability to heal itself. Various therapies may include bodywork and postural adjustments such as **chiropractic** and **Rolfing** work, in

addition to physical therapy and gentle exercise routines. Herbal remedies and **nutritional supplements** may be used to aid the healing process and reduce symptoms. **Acupuncture** may be used for pain relief, and **yoga** is a low-impact exercise routine that increases flexibility, good alignment, and strength.

Prevention

The best prevention for knee injuries is being aware of activities that carry high risks for knee injuries and acting carefully. The knees can be strengthened by evenly building the muscles in the quadriceps and hamstrings. Increasing flexibility in the body through stretching can also help reduce injuries. Properly fitting shoes and other sports equipment are essential for preventing injury as well. Finally, before engaging in activities that stress the knee, a thorough and gradual warm–up routine, including aerobic activity and stretching, will lessen the chances of knee injury.

General life-style habits are also recommended to reduce the risk for knee injuries. These include maintaining a health height-to-weight ratio (commonly called the **body mass index**); exercising on a regular basis (to keep the knees and the surrounding materials strong and flexible); warming up before exercising and cooling down after exercising; not over exercising the knees if they are hurting; and using protective devices when involved in high-risk sports (such as knee pads in basketball). It is also important to wear a seat belt and harness while driving because kneecap injuries are common when automobiles crash into other cars and objects along the road.

Knee replacement

Definition

Knee replacement is a procedure in which the surgeon removes damaged or diseased parts of the patient's knee joint and replaces them with new artificial parts. The operation itself is called knee **arthroplasty**. Arthroplasty comes from two Greek words—*arthros*, or joint, and *plassein*, "to form or shape." The artificial joint itself is called a prosthesis. Most knee prostheses have four components, or parts, and are made of a combination of metal and plastic or metal and ceramic.

WWW.BOOKBAZ.IR

Purpose

Knee arthroplasty has two primary purposes: **pain** relief and improved functioning of the knee joint. Because of the importance of the knee to a person's ability to stand upright, improved joint functioning includes greater stability in the knee.

Pain relief

Total knee replacement, or TKR, is considered major surgery. Therefore, it is usually not considered a treatment option until the patient's pain cannot be managed any longer by more conservative treatment.

Pain in the knee may be either a sudden or gradual development, depending on the cause of the pain. Knee pain resulting from **osteoarthritis** and other degenerative disorders may develop gradually over a period of years. On the other hand, pain resulting from an athletic injury or other traumatic damage to the knee, or from such conditions as **infectious arthritis** or **gout**, may come on suddenly. Because the structure of the knee is complex and many different disorders or conditions can cause knee pain, the cause of the pain must be diagnosed before joint replacement surgery can be discussed as an option.

Joint function

Restoration of joint function and stability is the other major purpose of knee replacement surgery. It is helpful to have a brief outline of the major structures in the knee joint in order to understand the types of disorders and injuries that can make joint replacement necessary as well as to understand the operation itself.

The knee is the largest joint in the human body, as well as one of the most vulnerable. Unlike the hip joint, which is partly protected by the bony structures of the pelvis, the knee joint is not shielded by any other parts of the skeleton. In addition, the knee joint must bear the weight of the upper body as well as the stresses and shocks carried upward through the feet when a person walks or runs. Moreover, the knee is essentially a hinge joint, designed to move primarily backward and forward; it is not a ball-and-socket joint like the hip, which can swivel and rotate in a variety of directions. Many **knee injuries** result from stresses caused by twisting or turning movements, particularly when the foot remains in one position while the upper body changes direction rapidly, as in basketball, tennis, or skiing.

The normal knee joint consists of a bone, the patella or kneecap, and a set of tendons, ligaments, and cartilage disks that connect the femur, or thighbone, to the lower leg. There are two bones in the lower leg, the tibia, which is sometimes called the shinbone; and the fibula, a smaller bone on the outside of the lower leg. There are two collateral ligaments on the outside of the knee joint that connect the femur to the tibia and fibula respectively. These ligaments help to control the stresses of side-to-side movements on the knee. The patella—a triangular bone at the front of the knee—is attached by tendons to the quadriceps muscles of the thigh. This tendon allows a person to straighten the knee. Two additional tendons inside the knee stretch between the femur and the tibia to prevent the tibia from moving out of alignment with the femur. Cartilage, which is a whitish elastic tissue that allows bones to glide smoothly against each other, covers the ends of the femur, tibia, and fibula as well as the surfaces of the patella. In addition to the cartilage that covers the bones, the knee joint also contains two crescent-shaped disks of cartilage known as menisci (singular, meniscus), which lie between the lower end of the femur and the upper end of the tibia and act as **shock** absorbers or cushions. The entire joint is surrounded by a thick layer of protective tissue known as the joint capsule.

Disorders and conditions that may lead to knee replacement surgery include:

- Osteoarthritis (OA). Osteoarthritis is a disorder in which the cartilage in the knee joint gradually breaks down, allowing the surfaces of the bones to rub directly against each other. The patient experiences swelling, pain, inflammation, and increasing loss of mobility. OA most often affects adults over age 45 and is thought to result from a combination of wear and tear on the joint, lifestyle, and genetic factors. Arthritis is the most common cause of joint damage requiring knee replacement.
- Rheumatoid arthritis (RA). Rheumatoid arthritis is a disease that begins earlier in life than OA and affects the whole body. Women are three times as likely as men to develop RA. Its symptoms are caused by the immune system's attacks on the body's own cells and tissues. Patients with RA often suffer intense pain even when they are not putting weight on the affected joints.
- Trauma. Damage to the knee from a fall, automobile accident, or workplace or athletic injury may trigger the process of cartilage breakdown inside the joint. Trauma is a common cause of damage to the knee joint. Some traumatic injuries are caused by repetitive motion or overuse of the knee joint, such as bursitis and so-called runner's knee. Other traumatic injuries are caused by sudden twisting of the knee, a direct blow to a bent knee, or being tackled from the side in football.

There are several factors that increase a person's risk of eventually requiring knee replacement surgery. While some of these factors cannot be avoided, others

KEY TERMS

Analgesic—A medication given to relieve pain.

Arthroplasty—The medical term for surgical replacement of a joint. Arthroplasty can refer to hip as well as knee replacement.

Arthroscope—An instrument that contains a miniature camera and light source mounted on a flexible tube. It allows a surgeon to see the inside of a joint or bone during surgery.

Autologous blood—The patient's own blood, drawn and set aside before surgery in case a transfusion is needed during surgery.

Biomechanics—The application of mechanical laws to the structures in the human body, such as measuring the force and direction of stresses on a joint.

Bursitis—Inflammation of a bursa, which is a sac-like cavity filled with fluid that protects the tissues around certain joints in the body from friction. Bursitis of the knee frequently develops as a result of activities requiring frequent bending and kneeling, such as housecleaning.

Cartilage—A whitish elastic connective tissue that allows the bones forming the knee joint to move smoothly against each other.

Cortisone—A steroid compound used to treat autoimmune diseases and inflammatory conditions. It is sometimes injected into a joint to relieve the pain of arthritis.

Debridement—Surgical removal of foreign material and dead or contaminated tissue from a wound or the area of an incision.

Disease-modifying antirheumatic drugs (DMARDs)—A group of medications that can be given to slow or stop the progression of rheumatoid arthritis. DMARDs include such drugs as oral or injectable gold, methotrexate, leflunomide, and penicillamine.

Fibula—The smaller of the two bones in the lower leg.

Ligament—A band of fibrous tissue that connects bones to other bones or holds internal organs in place.

Meniscus (plural, menisci)—One of two crescent-shaped pieces of cartilage attached to the upper surface of the tibia. The menisci act as shock absorbers within the knee joint.

Nonsteroidal anti-inflammatory drugs (NSAIDs)—A group of analgesics that also reduce inflammation when used over a period of time. NSAIDs are often given to patients with osteoarthritis.

Orthopedics (sometimes spelled orthopaedics)—The branch of surgery that treats deformities or disorders affecting the musculoskeletal system.

Orthotics—Shoe inserts that are intended to correct an abnormal or irregular gait or walking pattern. They are sometimes prescribed to relieve gait-related knee pain.

Patella—The kneecap; a triangular bone located at the front of the knee.

Prosthesis (plural, prostheses)—An artificial device that substitutes for or supplements a missing or damaged body part. Prostheses may be either external or implanted inside the body.

Quadriceps muscles—A set of four muscles on each leg located at the front of the thigh. The quadriceps straighten the knee and are used every time a person takes a step.

Tibia—The larger of two leg bones that lie beneath the knee. The tibia is sometimes called the shin bone.

can be corrected through lifestyle changes. Specific risk factors include:

- Genetics. Both OA and RA tend to run in families. One study done in France reported that the genetic factors affecting osteoarthritis in the knee can be traced back almost 8,000 years. Both OA and RA, however, are polygenic disorders, which means that more than one gene is involved in transmitting susceptibility to these forms of arthritis.
- Age. Knee cartilage becomes thinner and weaker with age, even in people who have no family history of arthritis.
- Gender. Women athletes have three times as many knee injuries as men. At present, orthopedic specialists are conducting studies to determine the cause(s) of this difference. Some doctors think it is related to the fact that most women have wider hips than most men, which results in a different pattern of stresses on the knee joint. Others think that the ligaments in women's knees tend to loosen more easily.
- Biomechanical factors. Biomechanics refers to the study of body structures in terms of the laws of mechanics, such as measuring the forces that affect the operation of a joint. Biomechanical studies have

WWW.BOOKBAZ.IR

shown that people with certain types of leg or foot deformities, such as bowlegs or difference in leg length, are at increased risk of knee disorders because the stresses on the knee joint are not distributed normally.

- Gait-related factors. Gait refers to a person's pattern of motion when walking or running. Some people walk with their feet turned noticeably outward or inward; others tend to favor either the heel or the toe when they walk, which makes their gait irregular. Any of these factors can increase strain on the knee joint.
- Shoes. Poorly fitted or worn-out shoes contribute to knee strain by increasing the force transmitted upward to the knee when the foot strikes the sidewalk or other hard surface. They also introduce or increase irregularities in gait. Women's high-heeled shoes are particularly harmful to the knee joint because they do not cushion the foot, and they cause prolonged tightening and fatigue of the leg muscles.
- Work or other activities that involve jumping, jogging, or squatting. Jogging tends to loosen the ligaments that hold the parts of the knee joint in alignment, while jumping increases the shock on the knee joint and the risk of twisting or tearing the knee joint when the person lands. Squatting can increase the forces on the knee joint as much as eight times body weight.

Demographics

According to the American Academy of Orthopaedic Surgeons (AAOS), there are about 300,000 knee replacement operations performed each year in the United States. Although about 70% of these operations are performed in people over the age of 65, a growing number of knee replacements are being done in younger patients. Most surgeons expect to see the proportion of knee arthroplasties performed in younger patients continue to rise. One reason for this trend is improvements in surgical technique, as well as the design and construction of knee prostheses since the first knee replacement was performed in 1968. Minimally invasive surgical techniques are allowing knee replacements to be performed with shorter recovery times, fewer complications, and less pain. A second reason is people's changing attitudes toward **aging** and their expectations of an active life after retirement. Fewer are willing to endure years of discomfort or resign themselves to a restricted level of activity.

In terms of gender and racial differences, women are slightly more likely to seek knee replacement surgery than men, and Caucasians in the United States are more likely to have the operation than African Americans. Researchers have suggested that one reason for the racial difference is a difference in social networks. People in general are influenced in their health care decisions by the experiences and opinions of friends or family members, and Caucasians are more likely than African Americans to know someone who has had knee replacement surgery.

Description

Knee replacement surgery is performed by an orthopedic surgeon, an MD who has received advanced training in surgical treatment of disorders of the musculoskeletal system. Qualification for this specialty in the United States required a minimum of five years of training after medical school. Most orthopedic surgeons who perform joint replacements have had additional specialized training in these specific procedures.

Knee replacement surgery can be performed in a general hospital with a department of **orthopedic surgery**, but is also performed in specialized clinics or institutes for joint disorders.

The length and complexity of a total knee replacement operation depend in part on whether both knee joints are replaced during the operation or only one. Such disorders as osteoarthritis usually affect both knees, and some patients would rather not undergo surgery twice. Replacement of both knees is known as bilateral TKR, or bilateral knee arthroplasty. Bilateral knee replacement seems to work best for patients whose knees are equally weak or damaged. Otherwise, most surgeons recommend operating on the more painful knee first, so that the patient will have one strong leg to help him or her through the recovery period following surgery on the second knee. The disadvantages of bilateral knee replacement include a longer period of time under **anesthesia**; a longer hospital stay and recovery period at home; and a greater risk of severe blood loss and other complications during surgery.

If the operation is on only one knee, it will take two to four hours. The patient may be given a choice of general, spinal, or epidural anesthesia. An epidural anesthetic, which is injected into the space around the spinal cord to block sensation in the lower body, causes less blood loss and also lowers the risk of **blood clots** or breathing problems after surgery. After the patient is anesthetized, the surgeon will make an incision in the skin over the knee and cut through the joint capsule. A standard incision may be used, or minimally invasive surgical techniques may dictate a more limited incision be utilized. In either case, the surgeon must be careful in working around the tendons and ligaments inside the

joint. Knee replacement is a more complicated operation than **hip replacement** because the hip joint does not depend as much on ligaments for stability. The next step is cutting away the damaged cartilage and bone at the ends of the femur and tibia. The surgeon reshapes the end of the femur to receive the femoral component, or shell, which is usually made of metal and attached with bone cement.

After the femoral part of the prosthesis has been attached, the surgeon inserts a metal component into the upper end of the tibia. This part is sometimes pressed rather than cemented in place. If it is a cementless prosthesis, the metal will be coated or textured so that new bone will grow around the prosthesis and hold it in place. A plastic plate called a spacer is then attached to the metal component in the tibia. The plastic allows the femur and tibia to move smoothly against each other.

Lastly, another plastic component is glued to the rear of the patella, or kneecap. This second piece of plastic prevents friction between the kneecap and the other parts of the prosthesis. After all the parts of the prosthesis have been implanted, the surgeon will check them for proper positioning, make certain that the tendons and ligaments have not been damaged, wash out the incision with sterile saline solution, and close the incision.

Diagnosis

Patient history

The first part of a diagnostic interview for knee pain is the careful taking of the patient's history. The doctor will ask not only for a general medical history, but also about the patient's occupation, **exercise** habits, past injuries to the knee, and any gait-related problems. The doctor will also ask detailed questions about the patient's ability to move or flex the knee; whether specific movements or activities make the pain worse; whether the pain is sharp or dull; its location in the knee; whether the knee ever buckles or catches; and whether there are clicking or popping sounds inside the joint.

Diagnostic tests

PHYSICAL EXAMINATION OF THE KNEE. Following the history, the doctor will examine the knee itself. The knee will be checked for swelling, reddening, **bruises**, breaks in the skin, lumps, or other unusual features while the patient is standing. The doctor will also make note of the patient's posture, including whether the patient is bowlegged or knock-kneed. The patient may be asked to walk back and forth so that the doctor can check for gait abnormalities.

In the second part of the **physical examination**, the patient lies on an examining table while the doctor palpates (feels) the structures of the knee and evaluates the strength or tightness of the tendons and ligaments. The patient may be asked to flex one knee and straighten the leg or turn the knee inward and outward so that the doctor can measure the range of motion in the joint. The doctor will also ask the patient to lie still while he or she moves the knee in different directions.

IMAGING STUDIES. The doctor will order one or more imaging studies in order to narrow the diagnosis. A radiograph or x-ray is the most common, but is chiefly useful in showing **fractures** or other damage to bony structures. X-ray studies are usually supplemented by other imaging techniques in diagnosing knee disorders. A computed tomography, or CAT scan, which is a specialized type of x-ray that uses computers to generate three-dimensional images of the knee joint, is often helpful in evaluating malformations of the joint. **Magnetic resonance imaging** (MRI) uses a large magnet, radio waves, and a computer to generate images of the knee joint. The advantage of an MRI is that it reveals injuries to ligaments, tendons, and menisci as well as damage to bony structures.

ASPIRATION. Aspiration is a procedure in which fluid is withdrawn from the knee joint by a needle and sent to a laboratory for analysis. It is done to check for infection in the joint and to draw off fluid that is causing pain. Aspiration is most commonly done when the knee has swelled up suddenly, but may be performed at any time. Blood in the fluid usually indicates a fracture or torn ligament; the presence of bacteria indicates infection; the presence of uric acid crystals indicates gout. Clear, straw-colored fluid suggests osteoarthritis.

ARTHROSCOPY. **Arthroscopy** can be used to treat knee problems as well as diagnose them. An arthroscope consists of a miniature camera and light source mounted on a flexible fiberoptic tube. It allows the surgeon to look into the knee joint. To perform an arthroscopy, the surgeon will make two to four small incisions known as ports. One port is used to insert the arthroscope; the second port allows insertion of miniaturized surgical instruments; the other ports drain fluid from the knee. Sterile saline fluid is pumped into the knee to enlarge the joint space and make it easier for the surgeon to view the knee structures and to cut, smooth, or repair damaged tissue.

Preparation

Knee replacement surgery requires extensive and detailed preparation on the patient's part because it affects so many aspects of life.

Legal and financial considerations

In the United States, physicians and hospitals are required to verify the patient's insurance benefits before surgery and to obtain precertification from the patient's insurer or from Medicare. Without health insurance, the total cost of a knee replacement is very expensive. In addition to insurance documentation, patients are legally required to sign an informed consent form prior to surgery. Informed consent signifies that the patient is a knowledgeable participant in making healthcare decisions. The doctor will discuss all of the following with the patient before he or she signs the form: the nature of the surgery; reasonable alternatives to the surgery; and the risks, benefits, and uncertainties of each option. Informed consent also requires the doctor to make sure that the patient understands the information that has been given.

Medical considerations

Patients are asked to do the following in preparation for knee replacement surgery:

- Get in shape physically by doing exercises to strengthen or increase flexibility in the knee joint. Many clinics and hospitals distribute illustrated pamphlets of preoperation exercises.
- Lose weight if the surgeon recommends it.
- Quit smoking. Smoking weakens the cardiovascular system and increases the risks that the patient will have breathing difficulties under anesthesia.
- Make donations of one's own blood for storage in case a transfusion is necessary during surgery. Known as autologous blood donation, this procedure has the advantage of avoiding the risk of transfusion reactions or transmission of diseases from infected blood donors.
- Check the skin of the knee and lower leg for external infection or irritation, and check the lower leg for signs of swelling. If either is noted, the surgeon should be contacted for instructions about preparing the skin for the operation.
- Have necessary dental work completed before the operation. This precaution is necessary because small numbers of bacteria enter the bloodstream whenever a dentist performs any procedure that causes the gums to bleed. Bacteria from the mouth can be carried to the knee area and cause an infection.
- Discontinue taking birth control pills and any anti-inflammatory medications (aspirin or NSAIDs) two weeks before surgery. Most doctors also recommend discontinuing any alternative herbal preparations at this time, as some of them interact with anesthetics and pain medications.

Lifestyle changes

Knee replacement surgery requires a long period of recovery at home after leaving the hospital. Since the patient's physical mobility will be limited, he or she should do the following before the operation:

- Arrange for leave from work, help at home, help with driving, and similar tasks and commitments.
- Obtain a handicapped parking permit.
- Check the house or apartment thoroughly for needed adjustments to furniture, appliances, lighting, and personal conveniences. People recovering from knee replacement surgery must avoid kneeling and minimize bending, squatting, and any risk of falling. There are several good guides available that describe household safety and comfort considerations in detail.
- Stock up on nonperishable groceries, cleaning supplies, and similar items in order to minimize shopping.
- Have a supply of easy-care clothing with elastic waistbands and simple fasteners in front rather than complicated ties or buttons in the back. Women may find knit dresses that pull on over the head or wraparound skirts easier to put on than slacks or skirts that must be pulled up over the knees. Shoes should be slip-ons or fastened with Velcro.

Many hospitals and clinics now have "pre-op" classes for patients scheduled for knee replacement surgery. These classes answer questions about the operation and what to expect during recovery and also provide an opportunity for patients to share concerns and experiences. Studies indicate that patients who have attended pre-op classes are less anxious before surgery and generally recover more rapidly.

Aftercare

Aftercare following knee replacement surgery begins while the patient is still in the hospital. Most patients will remain there for 5 to 10 days after the operation. During this period, the patient will be given fluids and antibiotic medications intravenously to prevent infection. Medications for pain will be given every three to four hours or through a device known as a

PCA (patient-controlled anesthesia). The PCA is a small pump that delivers a dose of medication into the IV when the patient pushes a button. To get the lungs back to normal functioning, a respiratory therapist will ask the patient to **cough** several times a day or breathe into blow bottles.

Aftercare during the hospital stay is also intended to lower the risk of a venous thromboembolism (VTE), or blood clot in the deep veins of the leg. Prevention of VTE involves medications to thin the blood, exercises for the feet and ankles while lying in bed, and wearing thromboembolic deterrent (TED) or **deep vein thrombosis** (DVT) stockings. TED stockings are made of nylon (usually white) and may be knee-length or thigh-length. They help to reduce the risk of a blood clot forming in the leg vein by putting mild pressure on the veins.

Physical therapy is also begun during the patient's hospital stay, often on the second day after the operation. The physical therapist will introduce the patient to using a cane or crutches and explain how to manage such activities as getting out of bed or showering without dislocating the new prosthesis. In most cases the patient will spend some time each day on a continuous passive motion (CPM) machine, which is a device that repeatedly bends and straightens the leg while the patient is lying in bed. In addition to increasing the patient's level of physical activity each day, the physical therapist will help the patient select special equipment for recovery at home. Commonly recommended devices include tongs or reachers for picking up objects without bending too far, a sock cone and special shoehorn, and bathing equipment.

Following **discharge from the hospital**, the patient may go to a skilled nursing facility, **rehabilitation** center, or home. Patients who have had bilateral knee replacement are unlikely to be sent directly home. Ongoing physical therapy is the most important part of recovery for the first four to five months following surgery. Most HMOs in the United States allow home visits by a home health aide, visiting nurse, and physical therapist for three to four weeks after surgery. Some hospitals allow patients to borrow a CPM machine for use at home for a few weeks. The physical therapist will monitor the patient's progress as well as suggest specific exercises to improve strength and range of motion. After the home visits, the patient is encouraged to take up other forms of low-impact physical activity in addition to the exercises; swimming, walking, and pedaling a stationary bicycle are all good ways to speed recovery. The patient may take a mild medication for pain (usually **aspirin** or ibuprofen) 30–45 minutes before an exercise session if needed.

The patient will be instructed to notify his or her dentist about the knee replacement so that extra precautions can be taken against infection resulting from bacteria getting into the bloodstream during dental work. Some surgeons ask patients to notify them whenever the dentist schedules a **tooth extraction**, root canal, or periodontal work.

Results

Normal results include relief of chronic pain in the knee and greater range of motion in the knee joint. Realistically, however, the patient should not expect complete restoration of function in the knee, and will usually be advised to avoid contact sports, skiing, jogging, or other athletic activities that strain the knee joint.

Mild swelling of the leg may occur for as long as three to six months after surgery. It can be treated by elevating the leg, applying an ice pack, and wearing compression stockings.

One commonplace side effect of TKR is that knee prostheses sometimes set off metal detectors in airports and high-security buildings because of their large metal content. Patients who fly frequently or whose occupations require security clearance should ask their doctor for a wallet card certifying that they have a knee prosthesis.

The patient can expect a cemented knee prosthesis to last about 10–15 years, although many still function well as long as 20 years later. Cementless prostheses have not been in use long enough for reliable evaluations of their long-term durability. When the prosthesis wears out or becomes loose, it is replaced in a procedure known as knee revision surgery.

Risks

Serious risks associated with TKR include the following:

- Loosening or dislocation of the prosthesis. The risk of dislocation varies, depending on the type of prosthesis used, the patient's level of activity, and the previous condition of the knee joint.
- Deep vein thrombosis (DVT). There is some risk (about 1.5% in the United States) of a clot developing in the deep vein of the leg after knee replacement surgery because the blood supply to the leg is cut off by a tourniquet during the operation. The blood-thinning medications and TED

WWW.BOOKBAZ.IR

stockings used after surgery are intended to minimize the risk of DVT.

- Infection. The risk of infection is minimized by storing autologous blood for transfusion and administering intravenous antibiotics after surgery. The rate of infection following knee replacement is about 1.89%. Factors that increase the risk of infection after TKR include poor nutritional status, diabetes, obesity, a weakened immune system, and a history of smoking.
- Heterotopic bone. Heterotopic bone is bone that develops at the lower end of the femur after knee replacement surgery. It is most likely to develop in patients whose knee joints developed an infection. Heterotopic bone can cause stiffness and pain and usually requires revision surgery.

The 30-day mortality rate following total knee arthroplasty was 0.25%. The overall frequency of complications in this time period was 4.5%. The rate of complications doubled in patients over 70.

A 2001 study published by the Mayo Clinic reviewed the records of 22,540 patients who had knee replacements between 1969 and 1997. The mortality rate within 30 days of surgery was 0.21%, or 47 patients. Forty-three of the 47 patients had preexisting cardiovascular or lung disease. Patients who had bilateral knee operations had a higher mortality rate than those who had not.

Alternatives

Nonsurgical alternatives

MEDICATION. The most common conservative alternatives to knee replacement surgery are **analgesics**, or painkilling medications. Most patients who try medication for knee pain begin with an over-the-counter NSAID such as ibuprofen (Advil). If the pain cannot be controlled by nonprescription analgesics, the doctor may give the patient cortisone injections, which relieve the pain of arthritis by reducing inflammation. Unfortunately, the relief provided by cortisone tends to diminish with each injection; moreover, the drug can produce serious side effects.

If the knee pain is caused by **rheumatoid arthritis**, a group of medications known as disease-modifying **antirheumatic drugs**, or DMARDs, may help to slow or stop the progress of the disease. They work by suppressing or interfering with the immune system. DMARDs include such drugs as penicillamine, methotrexate, oral or injectable gold, hydroxychloroquine, leflunomide, and sulfasalazine. DMARDs are not suitable for all patients with RA, however, as they sometimes have serious side effects. In addition, some of them are slow-acting and may take several months to work before the patient feels some relief.

LIFESTYLE CHANGES. A second alternative to knee surgery is lifestyle changes. Losing weight helps to reduce **stress** on the knee joint. Giving up specific sports or other activities that damage the knee, such as jogging, tennis, high-impact aerobics, or stair-climbing exercise machines, may control the pain enough to make surgery unnecessary. Wearing properly fitted shoes and avoiding high heels and other extreme styles can also help to control pain and minimize further damage to the knee.

BRACES AND ORTHOTICS. Some patients with unstable knees are helped by functional braces or knee supports that are designed to keep the kneecap from slipping out of place. Orthotics, which are inserts placed inside shoes, are often helpful to patients whose knee problems are related to their gait. Orthotics are designed either to correct the position of the foot in order to keep it from turning too far outward or inward, or to correct problems in the arch of the foot. Some orthotics are made of soft material that cushions the foot and are particularly helpful for patients with osteoarthritis or diabetes.

Complementary and alternative (CAM) approaches

Complementary and alternative therapies are not substitutes for arthroscopy or joint replacement surgery, but some have been shown to relieve physical pain before or after surgery, or to help patients cope more effectively with the emotional and psychological stress of a major operation. **Acupuncture**, **chiropractic**, hypnosis, and mindfulness **meditation** have been used successfully to relieve the pain of osteoarthritis as well as postoperative discomfort. According to Dr. Marc Darrow, author of *The Knee Sourcebook*, a plant extract called RA-1, which is used in **Ayurvedic medicine** to treat arthritis, relieved pain and leg swelling in patients participating in a randomized trial. Alternative approaches that have helped patients maintain a positive mental attitude include meditation, **biofeedback**, and various relaxation techniques.

Surgical alternatives

Arthroscopy is the most common surgical alternative to knee replacement. It should be understood, however, as a way to postpone TKR rather than avoid it completely. The arthroscopic procedure most

often used to treat knee pain from osteoarthritis is **debridement**, in which the surgeon cuts or scrapes away damaged structures or tissues until healthy tissue is reached. Most patients who have had arthroscopic debridement have been able to postpone TKR for three to five years.

Cartilage transplantation is a procedure in which small bone plugs with cartilage are removed from a part of the patient's knee where the cartilage is still healthy and transplanted to the area in which cartilage has been damaged. Another form of cartilage transplantation involves two operations, one to remove cartilage cells from the patient's knee for culture in a laboratory, and a second operation to place the new cells within the damaged part of the knee. The cultured cells are covered with a thin layer of tissue to hold them in place. After surgery, the cartilage cells multiply to form new cartilage inside the knee. Unfortunately, neither form of cartilage transplantation is usually beneficial to patients with osteoarthritis; transplantation has been most successful in treating patients whose knee cartilage was damaged by sudden **trauma** rather than by gradual degeneration.

Kneecap removal

Definition

Kneecap removal, or patellectomy, is the surgical removal of the patella, commonly called the kneecap.

Description

The patella is the small bone that is in the front of the knee. It is a sesamoid bone, which means it is embedded in a joint capsule or tendon. The patella in an adult is about 2 inches (5 cm) across.

Kneecap removal is performed under either general or local **anesthesia** at a hospital or freestanding surgical center, by an orthopedic surgeon. The surgeon makes an incision around the kneecap. Then, the muscles and tendons attached to the kneecap are cut and the kneecap is removed. Next, the muscles are sewed back together, and the skin is closed with sutures or clips that stay in place about one week. Any hospital stay is generally brief.

Purpose

Kneecap removal is performed under three circumstances:

WWW.BOOKBAZ.IR

- when the kneecap is fractured or shattered, also called patella fracture
- when the kneecap dislocates easily and repeatedly, also called patella dislocation
- when degenerative arthritis of the kneecap causes extreme pain, also called patellar arthritis

A person of any age can break a kneecap in an accident. When the bone is shattered beyond repair, the kneecap is removed. No prosthesis or artificial replacement part is put in its place.

Dislocation of the kneecap is most common in young girls between the ages of 10 and 14. Initially, the kneecap will pop back into place of its own accord, but **pain** may continue. If dislocation occurs too often, or the kneecap does not go back into place correctly, the patella may rub the other bones in the knee, causing an arthritis-like condition. Some people are born with **birth defects** that cause the kneecap to dislocate frequently.

Degenerative arthritis of the kneecap, also called patellar arthritis or *chondromalacia patellae*, can cause enough pain that it is necessary to remove the kneecap. As techniques of joint replacement have improved, arthritis in the knee is more frequently treated with total **knee replacement**.

Preparation

Prior to surgery, x rays and other diagnostic tests are done on the knee to determine if removing the kneecap is the appropriate treatment. Preoperative blood and urine tests are also done.

Aftercare

Pain relievers may be prescribed for a few days. The patient will initially need to use a cane, or crutches, to walk. **Physical therapy** exercises to strengthen the knee should be begun immediately. Driving should be avoided for several weeks. Full recovery can take months.

Risks

Risks involved with kneecap removal are similar to those that occur in any surgical procedure, mainly allergic reaction to anesthesia, excessive bleeding, and infection.

People who have had their kneecap removed for degenerative arthritis and then later have to have a total knee replacement are more likely to have problems with the stability of their artificial knee than those who only have total knee replacement. This is because the realigned muscles and tendons provide less support once the kneecap has been removed.

People who have kneecap removal because of a broken bone or repeated **dislocations** have the best chance for complete recovery. Those who have this operation because of arthritis may have less successful results and later need a total knee replacement.

KEY TERMS

Degenerative arthritis, or osteoarthritis—A non-inflammatory type of arthritis, usually occurring in older people, characterized by degeneration of cartilage, enlargement of the margins of the bones, and changes in the membranes in the joints.

KOH test

Definition

The KOH test takes its name from the chemical formula for potassium hydroxide (KOH), which is the substance used in the test. The test, which is also called a potassium hydroxide preparation, is done to rapidly diagnose **fungal infections** of the hair, skin, or nails. A sample of the infected area is analyzed under a

Thrush—A disease of the mouth, caused by *Candida albicans* and characterized by a whitish growth and ulcers. It can be diagnosed with the KOH test.

Tinea—A superficial infection of the skin, hair, or nails, caused by a fungus and commonly known as ringworm.

microscope following the addition of a few drops of potassium hydroxide.

Purpose

The primary purpose of the KOH test is the differential diagnosis of infections produced by dermatophytes and *Candida albicans* from other skin disorders. Dermatophytes are a type of fungus that invade the top layer of the skin, hair, or nails, and produce an infection commonly known as **ringworm**, technically known as tinea. It can appear as "jock itch" in the groin or inner thighs (tinea cruris); on the feet (tinea pedis); on the scalp and hair (tinea capitis); and on the nails (tinea unguium). Tinea versicolor appears anywhere on the skin and produces characteristic unpigmented patches. Tinea unguium affects the nails.

Similar symptoms of redness, scaling, and **itching** can be caused by other conditions, such as **eczema** and **psoriasis**. The KOH test is a quick, inexpensive test—often done in a physician's office—to see if these symptoms are caused by a dermatophyte. If a dermatophyte is found, treatment is started immediately; further tests are seldom necessary.

A yeast (candidal) infection of the skin or a mucous membrane, such as the mouth, often produces a white cheesy material at the infection site. This type of infection, known as thrush, is also identified with the KOH test.

Description

The KOH test involves the preparation of a slide for viewing under the laboratory microscope. KOH mixed with a blue-black dye is added to a sample from the infected tissues. This mixture makes it easier to see the dermatophytes or yeast under the microscope. The KOH dissolves skin cells, hair, and debris; the dye adds color. The slide is gently heated to speed up the action of the KOH. Finally the slide is examined under a microscope.

Dermatophytes are easily recognized under the microscope by their long branch-like structures. Yeast cells look round or oval. The dermatophyte that causes tinea versicolor has a characteristic spaghetti-and-meatballs appearance.

If the KOH test is done in the doctor's office, the results are usually available while the person waits. If the test is sent to a laboratory, the results will be ready the same or following day. The KOH test is covered by insurance when medically necessary.

Preparation

The physician selects an infected area from which to collect the sample. Scales and cells from the area are scraped using a scalpel. If the test is to be analyzed immediately, the scrapings are placed directly onto a microscope slide. If the test will be sent to a laboratory, the scrapings are placed in a sterile covered container.

Results

A normal, or negative, KOH test shows no fungi (no dermatophytes or yeast).

Abnormal results

Dermatophytes or yeast seen on a KOH test indicate the person has a fungal infection. Follow-up tests are usually unnecessary.

Korsakoff's psychosis *see* **Korsakoff's syndrome**

Korsakoff's syndrome

Definition

Korsakoff's syndrome is a memory disorder which is caused by a deficiency of vitamin B_1, also called thiamine.

WWW.BOOKBAZ.IR

Description

In the United States, the most common cause of thiamine deficiency is **alcoholism**. Other conditions which cause thiamine deficiency occur quite rarely, but can be seen in patients undergoing dialysis (a procedure used primarily for patients suffering from kidney failure, during which the patient's blood circulates outside of the body, is mechanically cleansed, and then is circulated back into the body), pregnant women with a condition called **hyperemesis gravidarum** (a condition of extreme morning sickness, during which the woman vomits up nearly all fluid and food intake), and patients after surgery who are given vitamin-free fluids for a prolonged period of time. Thiamine deficiency is an important cause of disability in developing countries where the main source of food is polished rice (rice with the more nutritious outer husk removed).

An associated disorder, Wernicke's syndrome, often precedes Korsakoff's syndrome. In fact, they so often occur together that the spectrum of symptoms produced during the course of the two diseases is frequently referred to as Wernicke-Korsakoff syndrome. The main symptoms of Wernicke's syndrome include ataxia (difficulty in walking and maintaining balance), **paralysis** of some of the muscles responsible for movement of the eyes, and confusion. Untreated Wernicke's will lead to **coma** and then death.

Causes and symptoms

One of the main reasons that alcoholism leads to thiamine deficiency has to do with the high-calorie nature of alcohol. A person with a large alcohol intake often, in essence, substitutes alcohol for other, more nutritive calorie sources. Food intake drops off considerably, and multiple vitamin deficiencies develop. Furthermore, it is believed that alcohol increases the body's requirements for B **vitamins**, at the same time interfering with the absorption of thiamine from the intestine and impairing the body's ability to store and use thiamine. Direct neurotoxic (poisonous damage to the nerves) effects of alcohol may also play some role.

Thiamine is involved in a variety of reactions which provide energy to the neurons (nerve cells) of the brain. When thiamine is unavailable, these reactions cannot be carried out, and the important end-products of the reactions are not produced. Furthermore, certain other substances begin to accumulate, and are thought to cause damage to the vulnerable neurons. The area of the brain believed to be responsible for the symptoms of Korsakoff's syndrome is called the diencephalon, specifically the structures called the mamillary bodies and the thalamus.

An individual with Korsakoff's syndrome displays much difficulty with memory. The main area of memory affected is the ability to learn new information. Usually, intelligence and memory for past events is relatively unaffected, so that an individual may remember what occurred 20 years previously, but is unable to remember what occurred 20 minutes ago. This memory defect is referred to as anterograde **amnesia**, and leads to a peculiar symptom called "confabulation," in which a person suffering from Korsakoff's fills in the gaps in his or her memory with fabricated or imagined information. For instance, a person may insist that a doctor to whom he or she has just been introduced is actually an old high school classmate, and may have a lengthy story to back this up. When asked, as part of a memory test, to remember the name of three objects which the examiner listed ten minutes earlier, a person with Korsakoff's may list three entirely different objects and be completely convincing in his or her certainty. In fact, one of the hallmarks of Korsakoff's is the person's complete unawareness of the memory defect, and complete lack of worry or concern when it is pointed out.

Diagnosis

Whenever someone has a possible diagnosis of alcoholism, and then has the sudden onset of memory difficulties, it is important to seriously consider the diagnosis of Korsakoff's syndrome. While there is no specific laboratory test to diagnose Korsakoff's syndrome in a patient, a careful exam of the individual's mental state should be rather revealing. Although the patient's ability to confabulate answers may be convincing, checking the patient's retention of factual information (asking, for example, for the name of the current president of the United States), along with the patient's ability to learn new information (repeating a series of numbers, or recalling the names of three objects ten minutes after having been asked to memorize them) should point to the diagnosis. Certainly a patient known to have just begun recovery from Wernicke's syndrome, who then begins displaying memory difficulties, would be very likely to have developed Korsakoff's syndrome. A **physical examination** may also show signs of Wernicke's syndrome, such as **peripheral neuropathy**.

Treatment

Treatment of both Korsakoff's and Wernicke's syndromes involves the immediate administration of thiamine. In fact, any individual who is hospitalized for any reason and who is suspected of being an alcoholic, should receive thiamine. The combined Wernicke-Korsakoff syndrome has actually been precipitated in

KEY TERMS

Amnesia—Inability to remember events or experiences. Memory loss. Includes: 1) Anterograde amnesia: inability to retain the memory of events occurring after the time of the injury or disease which brought about the amnesic state. 2) Retrograde amnesia: inability to recall the memory of events which occurred prior to the time of the injury or disease which brought about the amnesic state.

Confabulation—An attempt to fill in memory gaps by fabricating information or details.

Diencephalon—A part of the brain that binds the mesencephalon to the cerebral hemispheres. Considered by some as part of the brain stem.

alcoholic patients hospitalized for other medical illnesses, due to the administration of thiamine-free intravenous fluids (intravenous fluids are those fluids containing vital sugars and salts which are given to the patient through a needle inserted in a vein). Also, the vitamin therapy may be impaired by the feeding of carbohydrates prior to the giving of thiamine; since carbohydrates cannot be metabolized with thiamine.

Prognosis

Fifteen to twenty percent of all patients hospitalized for Wernicke's syndrome will die of the disorder. Although the degree of ataxia nearly always improves with treatment, half of those who survive will continue to have some permanent difficulty walking. The paralysis of the eye muscles almost always resolves completely with thiamine treatment. Recovery from Wernicke's begins to occur rapidly after thiamine is given. Improvement in the symptoms of Korsakoff's syndrome, however, can take months and months of thiamine replacement. Furthermore, patients who develop Korsakoff's syndrome are almost universally memory-impaired for the rest of their lives. Even with thiamine treatment, the memory deficits tend to be irreversible, with less than 20% of patients even approaching recovery. The development of Korsakoff's syndrome often results in an individual requiring a supervised living situation.

Prevention

Prevention depends on either maintaining a diet with a sufficient intake of thiamine, or supplementing an inadequate diet with vitamin preparations. Certainly, one of the most important forms of prevention involves treating the underlying alcohol **addiction**.

Kyphosis

Definition

Kyphosis is the extreme curvature of the upper back also known as a hunchback.

Description

The upper back bone (thoracic region), is normally curved forward. If the curve exceeds 50° it is considered abnormal (kyphotic).

Causes and symptoms

Kyphosis can be divided into three ages of acquisition—birth, old age, and the time in between.

- Spinal birth defects can result in a fixed, exaggerated curve. Vertebrae can be fused together, shaped wrong, extraneous, or partially missing. Congenital and hereditary defects in bone growth weaken bone and result in exaggerated curves wherever gravity or muscles pull on them. Dwarfism is such a defect.
- During life, several events can distort the spine. Because the natural tendency of the thoracic spine is to curve forward, any weakness of the supporting structures will tend in that direction. A diseased thoracic vertebra (a spine bone) will ordinarily crumble its forward edge first, increasing the kyphotic curve. Conditions that can do this include cancer, tuberculosis, Scheuermann's disease, and certain kinds of arthritis. Healthy vertebra will fracture forward with rapid deceleration injuries, such as in car crashes when the victim is not wearing a seat belt.
- Later in life, kyphosis is caused from osteoporosis, bone weakness, and crumbling forward.

WWW.BOOKBAZ.IR

This patient's spine shows excessive backward curvature at the level of the upper chest. *(Custom Medical Stock Photo, Inc.)*

The **stress** caused by kyphosis produces such symptoms as an increase in musculoskeletal pains, tension headaches, back aches, and joint pains.

Diagnosis

A quick look at the back will usually identify kyphosis. X rays of the spine will confirm the diagnosis and identify its cause.

Treatment

Congenital defects have to be repaired surgically. The procedures are delicate, complicated, and lengthy. Often orthopedic hardware must be placed to stabilize the back bone. At other times, a device called a Milwaukee brace can hold the back in place from the outside. Fitting Milwaukee braces comfortably is difficult because they tend to rub and cause sores.

KEY TERMS

Congenital—Present at birth.

Dwarfism—A congenital disease of bone growth that results in short stature and weak bones.

Orthopedic—Refers to surgery on the supporting structures of the body: bones, joints, ligaments, muscles.

Osteoporosis—A weakening of bones due to calcium loss that affects post-menopausal women.

Scheuermann's disease—Juvenile kyphosis due to damaged bone in the spinal vertebrae.

Kyphosis acquired during the younger years requires treatment directed at the cause, such as medications for **tuberculosis**. Surgical reconstruction or bracing may also be necessary.

Kyphosis induced by **osteoporosis** is generally not treated except to prevent further bone softening.

Prognosis

Congenital kyphosis may be alleviated to some extent by surgery and bracing. Kyphosis occurring later in life may worsen over time.

Prevention

Preventing osteoporosis is within the grasp of modern medicine. Menopausal women must start early with estrogen replacement, **calcium** supplementation, and appropriate **exercise**. The treatment must continue through the remainder of life. Evidence suggests that a high calcium intake even during younger years delays the onset of symptomatic osteoporosis. Dairy products are the major dietary sources of calcium.

Labyrinthitis

Definition

Labyrinthitis is an inflammatory disorder of the inner ear, or the system of passages called the bony labyrinth that contains the vestibular system, which senses changes of position to the head. The disorder is often a complication of **otitis media**. Derived from the Latin word labyrinthus, the medical condition called labyrinthitis is produced by the spread of bacterial or viral infections from the head or respiratory tract into the inner ear. A person with labyrinthitis will have irritation and swelling of the inner ear, along with a reduced ability to maintain their balance and a diminished ability to hear in one or both ears.

Demographics

Anyone can contract the various forms of labyrinthitis. Viral labyrinthitis is the most common form of the disorder. It is usually reported in adults from 30 to 60 years of age. The viral condition is rarely seen in children.

Description

Labyrinthitis is characterized by **dizziness** or feelings of **motion sickness** caused by disturbance of the sense of balance. Along with a balance disorder, people with labyrinthitis may also experience **hearing loss** and **tinnitus**. People who are getting over an upper respiratory tract infection (URI) often get labyrinthitis.

People at increased risk from labyrinthitis include those with previous **ear surgery**, frequent infections, alcohol abuse, tobacco use, **fatigue**, **stress**, dizziness or hearing loss, diabetes, **stroke**, migraine headaches, use of certain drugs (especially **aspirin**), **trauma** of the head or spine, ear disease, or high blood pressure.

Causes and symptoms

Causes

The disease agents that cause labyrinthitis may reach the inner ear by one of three routes:

- Bacteria may be carried from the middle ear or the membranes that cover the brain.
- Viruses that cause mumps, measles, influenza, and colds may reach the inner ear following an upper respiratory infection.
- Rubella virus can cause labyrinthitis in infants prior to birth.

The major cause of labyrinthitis is viral. Some of the viruses that can cause labyrinthitis are the cytomegalovirus, **mumps** virus, **rubella** virus, **influenza** virus, herpes simplex virus 1, and adenovirus. Other causes of labyrinthitis include severe stress, head injuries, **allergies**, medicine reactions, or toxic drugs.

Symptoms

The primary symptoms of labyrinthitis are vertigo (dizziness, abnormal sense of movements), accompanied by hearing loss (in one ear) and a sensation of ringing in one or both ears (called tinnitus). Vertigo occurs because the inner ear, part of the vestibular system that coordinates sensory inputs, controls the sense of balance as well as hearing. Difficulty focusing of the eyes is another symptom. Oftentimes patients have trouble sensing both linear and rotational motion. Some patients also experience nausea, **fever**, **anxiety**, **vomiting**, general sickness, and spontaneous eye movements (**nystagmus**) in the direction of the unaffected ear. Other symptoms include earache, weakness in the face (possibly on one side more than the other side), decreases in eyesight, and stiffness or

KEY TERMS

Labyrinth—The bony cavity of the inner ear.

Meniere's syndrome—A disease of the inner ear marked by recurrent episodes of vertigo and roaring in the ears lasting several hours. Its cause is unknown.

Otitis media—Inflammation of the middle ear. It can lead to labyrinthitis.

Vertigo—A sensation of dizziness marked by the feeling that one's self or surroundings are spinning or whirling.

pain in the neck. Inflammation in the middle ear (otitis media) can also occur. Bacterial labyrinthitis may produce a discharge from the infected ear.

A common side effect of labyrinthitis is anxiety. Such a problem can produce panic attacks, heart **palpitations**, and **tremors**. In serious cases, depression can happen.

Diagnosis

The diagnosis of labyrinthitis is based on a combination of the patient's symptoms and history—especially a history of a recent upper respiratory infection. The doctor will test the patient's hearing, and order a laboratory culture to identify the organism if the patient has a discharge. A complete physical and neurological examination will include the head and neck, especially in the areas of the otologic, ocular, and cranial nerves. The otologic examination will consist of looking for signs of **mastoiditis** (an infection of the temporal bone of the skull behind the ear), **cellulitis** (inflammation of connective tissue), or previous ear surgery, along with an inspection of the ear canal, the tympanic membrane, and the middle ear. The ocular exam should include an inspection of the eyes with respect to general motion and eyelid response, along with other abnormalities of vision. The neurologic exam will consist of an inspection in and about the cranial nerve.

If there is not a history of a recent infection, the doctor will order extra tests in order to exclude injuries to the brain or Meniere's disease. Possible tests include an electronystagmography (ENG), **electroencephalography** (EEG), head computed tomography (CT) scan, hearing test, and head **magnetic resonance imaging** (MRI) scan.

Treatment

Medication

Patients with minor labyrinthitis are initially given bed rest and plenty of fluids at home. They are asked to avoid sudden changes in position, not to read, avoid bright lights, and to gradually resume normal activities as symptoms decrease. They are prescribed **antibiotics**, either by mouth or intravenously to clear up the infection.

More pronounced symptoms of labyrinthitis may require care in a hospital or other health care facility. Intravenous fluids and medicines to control vomiting, dizziness, and nausea are also given. Patients may be given meclizine (Antivert, Bonine), scopolamine (Maldemar, Scopace, Transderm-Scop), or prochlorperazine (Compazine, Buccastem, Phenotil) for vertigo and nausea. For anxiety and depression, antidepressants or sedative-hypnotics (Valium) are given.

To treat labyrinthitis itself, selective serotonin-reuptake inhibitors have been found to be effective. They work by stimulating neural growth within the inner ear, along with relieving some of the symptoms like dizziness. **Corticosteroids**, such as prednisone, have also been shown to be an effective way to treat labyrinthitis during its early stages. When a virus causes labyrinthitis, antiviral medicines such as valacyclovir are used as early as possible so as not to permanently damage the inner ear. Vestibular **rehabilitation** therapy (VRT) is also provided to treat dizziness.

Surgery

Some patients require surgery to drain the inner and middle ear.

Supportive care

Patients with labyrinthitis should rest in bed for three to five days until the acute dizziness subsides. Patients who are dehydrated by repeated vomiting may need intravenous fluid replacement. In addition, patients are advised to avoid driving or similar activities for four to six weeks after the acute symptoms subside, because they may have occasional dizzy spells during that period.

Prognosis

Most patients with labyrinthitis recover completely within two to three weeks, although it often

WWW.BOOKBAZ.IR

takes five to six weeks for the vertigo to disappear completely and the patient's hearing to return to normal. To return completely back to normal conditions (without dizziness and balance problems) a recovery time of months or even a year or so is sometimes the case. Hearing usually returns to normal. In a few cases, the hearing loss is permanent, and other symptoms may never return to normal. Dizziness may continue with older patients.

Prevention

The most effective preventive strategy includes prompt treatment of ear and respiratory infections by medical professionals, as well as the monitoring of patients with mumps, **measles**, influenza, or colds for signs of dizziness or hearing problems.

A laceration is a traumatic break in the skin caused by a sharp object producing edges that may be jagged, dirty, or bleeding. The underlying tissue may also be severed. In such instances, the physician may place absorbable sutures in the tissue to help bring the edges together before the skin is sutured close. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Laceration repair

Definition

Laceration repair includes all the steps required to treat a wound in order to promote healing and minimize the risks of infection, premature splitting of sutures (dehiscence), and poor cosmetic result.

Purpose

A laceration is a wound caused by a sharp object producing edges that may be jagged, dirty, or bleeding. Lacerations most often affect the skin, but any tissue may be lacerated, including subcutaneous fat, tendon, muscle, or bone.

A laceration should be repaired if it:

- continues to bleed after application of pressure for 10–15 minutes
- is more than 0.125–0.25 in (0.3–0.6 cm) deep
- exposes fat, muscle, tendon, or bone
- causes a change in function surrounding the area of the laceration
- is dirty or has visible debris in it
- is located in an area where an unsightly scar is undesirable

Lacerations are less likely to become infected if they are repaired soon after they occur. Many physicians will not repair a laceration that is more than eight hours old because the risk of infection is too great.

Eleven sutures are necessary to close up the laceration on this person's forehead. *(Custom Medical Stock Photo, Inc.)*

Description

Primary care physicians, emergency room physicians, and surgeons usually repair lacerations. All physicians are trained in the basics of wound assessment, cleansing, and **anesthesia**. They are also familiar with the basic suturing techniques and have the experience required to attend to the details of wound repair—such as proper selection and preparation of equipment, careful wound preparation, appropriate use of specific closure methods, and effective patient education—required to avoid wound infection and excessive scarring.

Laceration repair is routinely performed in hospitals and clinics on an outpatient basis.

Laceration repair mends a tear in the skin or other tissue. The four goals of laceration repair are to stop bleeding, prevent infection, preserve function, and restore appearance.

The laceration is cleaned by removing any foreign material or debris. Removing **foreign objects** from penetrating **wounds** can sometimes cause bleeding, so this type of wound must be cleaned very carefully. The wound is then irrigated with saline solution and a disinfectant. The disinfecting agent may be mild soap or a commercial preparation. An antibacterial agent may be applied.

Once the wound has been cleansed, the physician anesthetizes the area of the repair. Most lacerations are anesthetized by local injection of lidocaine, with or without epinephrine, into the wound edges. Lidocaine without epinephrine is used in areas with limited blood supply such as fingers, toes, ears, penis, and nose, because epinephrine could cause constriction of blood vessels (vasoconstriction) and interfere with the supply of blood to the laceration site. Alternatively, a topical anesthetic combination such as lidocaine, epinephrine, and tetracaine may also be used.

The physician may trim edges that are jagged or extremely uneven. Tissue that is too damaged to heal must be removed (**debridement**) to prevent infection. If the laceration is deep, several absorbable stitches (sutures) are placed in the tissue under the skin to help bring the tissue layers together. Suturing also helps eliminate any pockets where tissue fluid or blood can accumulate. The skin wound is closed with sutures. Suture material used on the surface of a wound is usually non-absorbable and will have to be removed later. A light dressing or an adhesive bandage is applied for 24–48 hours. In areas where a dressing is not feasible, an antibiotic ointment can be applied. If the laceration is the result of a human or animal bite, if it is very dirty, or if the patient has a medical condition that alters wound healing, a broad-spectrum antibiotic may be prescribed.

Newer types of laceration repair do not require sutures. Materials such as staples or Dermabond glue may be used to hold the edges of a laceration together, allowing the edges to knit together.

Preparation

Preparation for laceration repair involves inspecting the wound and the underlying tendons or nerves to evaluate the risk of infection, the degree of tissue damage, the need for debridement, and its complexity. If hair is located in or around the wound, it is usually removed to minimize contamination and allow for good visibility of the wound. If nerves or tendons have been injured, a surgeon may be needed to complete the repair.

WWW.BOOKBAZ.IR

KEY TERMS

Debridement—The act of removing any foreign material and damaged or contaminated tissue from a wound to expose surrounding healthy tissue.

Dehiscence—A premature bursting open or splitting along natural or surgical suture lines. A complication of surgery that occurs secondary to poor wound healing.

Laceration—A torn, ragged, mangled wound.

Sutures—Materials used in closing a surgical or traumatic wound.

Vasoconstriction—The diminution of the diameter of blood vessels, leading to decreased blood flow to a part of the body.

Aftercare

The laceration is kept clean and dry for at least 24 hours after the repair. Light bathing is generally permitted after 24 hours if the wound is not soaked. The physician will provide directions for any special wound care. Sutures are removed three to 14 days after the repair is completed. Timing of suture removal depends on the location of the laceration and physician preference.

The repair should be examined frequently for signs of infection, which include redness, swelling, tenderness, drainage from the wound, red streaks in the skin surrounding the repair, chills, or **fever**. If any of these occur, the physician should be contacted immediately.

Risks

The most serious risk associated with laceration repair is infection. Risk of infection depends on the nature of the wound and the type of injury sustained. Infection risks are increased in wounds that are contaminated with soil or fecal matter; are the result of bites; have been open longer than one hour; or are located on the extremities or on the region between the thighs, genitalia, or other areas where opposing skin surfaces touch and may rub.

Results

All lacerations will heal with a scar. Wounds that are repaired with sutures are less likely to develop **scars** that are unsightly, but it cannot be predicted how wounds will heal and who will develop unsightly scars. **Plastic surgery** can improve the appearance of many scars.

Alternatives

The only alternative to laceration repair is to leave the wound without medical treatment. This increases the risk of infection, poor healing, and an undesirable cosmetic result.

Lacrimal duct obstruction

Definition

A lacrimal duct obstruction is a condition caused by a partial or complete blockage of the tear duct, the thin channel (small tube) that normally drains tears from the surface of the eye and into the nose. A blocked tear duct occurs usually when the drainage system between the inside corner of the eye and the inside of the nose is obstructed by something or does not properly open. When either case happens, tears on the surface of the eyes are not allowed to move into the nose so that they can be reabsorbed into the body or evaporated into the air. Consequently, the tear duct sac fills with tears. If not treated promptly, such a situation can lead to a watery, irritated eye that first becomes swollen and inflamed and, later, possibly infected.

Demographics

An obstruction of the tear duct is rarely found in healthy adults. When it does appear in an adult it usually results from an injury suffered in or around the eyes. However, tear duct blockage has been verified to be more prominent in older adults, being an age-related condition. The condition can also be present at birth, with about 6 to 20 out of 100 newborn babies having lacrimal duct obstruction. When this case arises, it is congenital and is called nasolacrimal duct obstruction.

Description

The lacrimal glands, located above each eyeball, produce tears. The tears flow over the eye, and then drain through the nasolacrimal ducts. A tiny hole at the inner edge of each eyelid marks the opening of the ducts, which lead to the lacrimal sacs located on the side of the nose. The tears pass from the sacs into the nasolacrimal ducts and then into the nose. Once in the nose, they are either reabsorbed by the body or evaporated into the air.

When a tear duct becomes obstructed, tears may spill over the eyelids and run down the face. Stagnant tears within the system can become infected, leading to recurrent red eyes and infections. Excessive tearing can also produce secondary skin changes on the lower eyelids.

Increased risks for acquiring lacrimal duct obstruction include:

- premature birth
- age and gender (females are more at risk than males; as are older people over younger ones)
- chronic eye infections (dacrosystitis)
- family history of blocked tear ducts
- previous cancer treatments (chemotherapy or radiation), especially of the face or head
- abnormal bone growth or tumors around the eyes
- chronic eye inflammation (conjunctivitis)
- previous surgeries of the eye or eyelid, along with nasal or sinus surgery
- use of glaucoma medications

Causes and symptoms

An obstructed lacrimal tear duct can result in inflammation and infection of the lacrimal sac. The area beneath the eyes next to the nose can become red, inflamed, and sensitive to the touch. The area usually is swollen, painful, and there may be a mucous discharge from the opening of the nasal corner of the eye. Blurred vision may also occur, along with bloody tears. Common complaints include **itching**, irritation, burning, redness, foreign body sensation, and tearing. Symptoms are worsened by cold weather, high winds, bright sunlight, and exposure to upper respiratory infections.

The first symptom to appear is usually excessive tearing. It may occur as the appearance of wet-looking eyes or grow as large as excessive amounts of tears running down the cheeks. Newborns have symptoms starting from a few days to a few weeks after being born. In all ages, symptoms include redness and inflammation around the eye or nose. Yellow mucus may appear from the corners of the eye. Eventually, eyelids may stick together. Infection is usually a latter-stage symptom, especially in the eyelids.

Children frequently have a congenital lacrimal duct obstruction. Six to ten percent of all children are born before their tear ducts are open. The unopened tear duct is caused by immature tissue at the end of the tear duct, which causes it not to open normally. Children may also acquire lacrimal duct obstruction due to infections, abnormal growth of the nasal bone, and undeveloped openings in the corners of the eyes.

In adults, a common cause of lacrimal duct obstruction is involution, which is progressive degeneration occurring naturally with advancing age, resulting in shriveling of organs or tissues. Other causes include:

- eyelid disorders
- infections by bacteria, viruses, fungi, and parasites
- inflammation

WWW.BOOKBAZ.IR

- regular use of eye drops or excessive use of nasal spray
- topical medications that treat eye problems
- systemic chemotherapy
- trauma from previous surgeries to the bone at the side of the nose
- injuries to the face
- abnormal development of the skull and face
- foreign bodies
- sinus disease
- nasal polyps
- cysts and stones
- malignant or benign tumors

Smoking tobacco products can also increase the likelihood of tear blockages.

Diagnosis

The medical professional will rely initially on the patient's medical history and a **physical examination**. If the primary symptom is excessive tearing, the first step is for the health care professional to determine if the overflow of tears is due to an increase in tear production or a decrease in tear drainage. Tests will establish the amount of tears being produced and whether the tears are draining normally. Such tests include the fluorescein dye disappearance (test for ability of tears to drain), irrigation and probing (test for ability to drain and presence of blockage), and dacryocystography or dacryoscintigraphy (test to indicate cause of blockage with use of medical scans).

Causes of increased tear production may include trichiasis, a disease in which the eyelashes produce constant irritation, and eyelid malpositions and diseases. If abnormal tear production is ruled out, then obstructions in tear drainage is the most likely cause of the excessive tearing. Additional observations of swollen lacrimal sac area and purulent eye discharge indicate that there may be a lacrimal duct infection present. To define the diagnosis, the lacrimal discharge may be cultured to determine possible infective agents, while various imaging techniques may be used to detect the type of obstruction. Dye tracer tests are also used to test for blockages.

Treatment

Lacrimal duct obstructions in children often resolve spontaneously, with 95% showing resolution before the child is one year old. Daily massaging (two to four times each day) of the lacrimal sac may help open the blockage. A topical antibiotic ointment may be applied if infection is present. If the blockage is not resolved after several weeks to months of this therapy, a physician may attempt forceful irrigation. Dilation, probing, and irrigation to open up the duct under general **anesthesia** or under a restraint is a last resort, after six months to one year or so of less invasive treatments. The dilation, probing, and irrigation technique is usually successful in the vast majority of the cases with children.

In adults, the condition is generally correctable, with conservative treatments usually recommended. The cause of the blockage and a person's age may make treatment more difficult. The infected or inflamed area may be massaged, with warm compresses applied to provide relief and speed the healing process. The health care provider may also irrigate the infected area. Topical antibiotic ointments and oral **antibiotics** are often applied to reduce infection. The use of **analgesics** such as **aspirin** may be recommended to control discomfort and reduce swelling.

The eyes can be kept clean by wiping drainage away from them. Moisten a cotton call or clean washcloth with warn water. Wipe carefully and gently once from the inner to the outer part of the eye. Repeat multiple times, if necessary; with a new cotton ball or washcloth. To clean eyelashes, use a gentle downward motion onto the eyelash with a moist cotton ball. If the eyelash contains dried substances, apply a warm, moistened cotton ball over the eye lash for a few minutes.

Minimally invasive treatments or surgeries may also be necessary if conservative measures fail to help. One such treatment is stenting or intubation. Tiny polyurethane- or silicone-based tubes are used to clear blockages or to widen narrowing of the tear ducts. The most frequent surgery is called an external dacryocystorhinostomy. An incision is made on the side of the nose so the surgeon can insert a stent.

In another treatment, balloon catheter dilation helps to resolve problems with passages narrowed by inflammation, scarring, or other related problems. In one such surgery, a complete reconstruction of the drainage system is performed. Called conjunctivodacryocystorhinostomy, it creates to new passageway (an artificial duct) for the tears to drain.

Procedures called endoscopic or endonasal are also sometimes used. Without making an incision, the surgeon inserts tiny instruments attached to cameras through the nasal opening to correct the problem.

As with children, the procedure called dilation, probing, and irrigation can also be effectively applied to adults.

KEY TERMS

Lacrimal duct—A short canal leading from a small orifice at the medial angle of each eyelid to the lacrimal sac.

Lacrimal gland—An almond-shaped gland that secretes tears.

Lacrimal sac—The dilated upper end of the nasolacrimal duct in which the lacrimal ducts empty.

Nasolacrimal duct—A channel that transmits tears from the lacrimal sac to the nose.

Purulent—Consisting of or containing pus.

Tear—A drop of the clear, salty fluid secreted by the lachrimal gland.

Trichiasis—A disease of the eye, in which the eyelashes, being turned in upon the eyeball, produce constant irritation by the motion of the lids.

Prognosis

Most adults respond positively to conservative treatments. If such approaches fail to clear the obstruction, surgical procedures are available, with success rates greater than 90%. The vast majority of children out grow the condition, and treatments are usually unnecessary. However, when treatments are necessary, they usually solve the problem.

Prevention

Lacrimal duct obstruction is not preventable. In many cases, the cause of a lacrimal duct obstruction is not known. Most of the cases are congenital (present at birth). However, there are several effective ways to minimize the chances of having a blockage of the tear ducts. For parents, if your child has blockage of the tear ducts, keep the baby away from winds, sunlight, and coldness.

For adults, always treat sinus or eye infections promptly. When engaging in strenuous **exercise** and activities (such as bicycling) or contact sports (such as hockey)—when injuries to the face are likely—always wear a helmet or protective eye gear. In addition, do not smoke tobacco products and do not abuse nasal sprays.

Lactate dehydrogenase isoenzymes test

Definition

The enzyme lactate dehydrogenase (also known as lactic dehydrogenase, or LDH) is found in the cells of almost all body tissues. The enzyme is especially concentrated in the heart, liver, red blood cells, kidneys, muscles, brain, and lungs. The total LDH can be further separated into five components or fractions labeled by number: LDH-1, LDH-2, LDH-3, LDH-4, and LDH-5. Each of these fractions, called isoenzymes, is used mainly by a different set of cells or tissues in the

WWW.BOOKBAZ.IR

body. For this reason, the relative amounts of a particular isoenzyme of LDH in the blood can provide valuable diagnostic information.

Purpose

The LDH isoenzymes test assists in differentiating **heart attack**, anemia, lung injury, or **liver disease** from other conditions that may cause the same symptoms (differential diagnosis).

Precautions

Strenuous **exercise** may raise levels of total LDH, specifically the isoenzymes LDH-1, LDH-2, and LDH-5. Alcohol, anesthetics, **aspirin**, **narcotics**, procainamide, fluorides, and mithramycin may also raise levels of LDH. Ascorbic acid (vitamin C) can lower levels of LDH.

Description

LDH is found in the cells of almost all body tissues. When certain conditions injure cells in tissues containing LDH, it is released into the bloodstream. Because LDH is so widely distributed throughout the body, analysis of total LDH will not help make a diagnosis of a particular disease. Because this enzyme is actually composed of five different isoenzymes, however, analysis of the different LDH isoenzyme levels in the blood can help in the diagnosis of some diseases.

The five LDH isoenzymes are: LDH-1, LDH-2, LDH-3, LDH-4, and LDH-5. In general, each isoenzyme is used mostly by the cells in a specific tissue. LDH-1 is found mainly in the heart. LDH-2 is primarily associated with the system in the body that defends against infection (reticuloendothelial system). LDH-3 is found in the lungs and other tissues, LDH-4 in the kidney, placenta, and pancreas, and LDH-5 in liver and striated (skeletal) muscle. Normally, levels of LDH-2 are higher than those of the other isoenzymes.

Certain diseases have classic patterns of elevated LDH isoenzyme levels. For example, an LDH-1 level higher than that of LDH-2 is indicative of a heart attack or injury; elevations of LDH-2 and LDH-3 indicate lung injury or disease; elevations of LDH-4 and LDH-5 indicate liver or muscle disease or both. A rise of all LDH isoenzymes at the same time is diagnostic of injury to multiple organs. For example, a heart attack with **congestive heart failure** may cause symptoms of lung and liver congestion. Advanced cancer and autoimmune diseases such as lupus can also cause this pattern.

One of the most important diagnostic uses for the LDH isoenzymes test is in the differential diagnosis of myocardial infarction or heart attack. The total LDH level rises within 24–48 hours after a heart attack, peaks in two to three days, and returns to normal in approximately five to ten days. This pattern is a useful tool for a delayed diagnosis of heart attack. The LDH-1 isoenzyme level, however, is more sensitive and specific than the total LDH. Normally, the level of LDH-2 is higher than the level of LDH-1. An LDH-1 level higher than that of LDH-2, a phenomenon known as "flipped LDH," is strongly indicative of a heart attack. The flipped LDH usually appears within 12–24 hours after a heart attack. In about 80% of cases, flipped LDH is present within 48 hours of the incident. A normal LDH-1/LDH-2 ratio is considered reliable evidence that a heart attack has not occurred.

It should be noted that two conditions might cause elevated LDH isoenzymes at the same time and that one may confuse the other. For example, a patient with **pneumonia** may also be having an acute heart attack. In this instance, the LDH-1 level would rise with the LDH-2 and LDH-3. Because of this complication, some laboratories measure only the LDH-1 and consider an elevated LDH level with LDH-1 higher than 40% to be diagnostic of heart damage. LDH isoenzymes test is not used much anymore for diagnosis of heart attack. Tests for the protein troponin, which is found in myocardial cells, have been found to be more accurate.

Preparation

This test requires a blood sample. The patient need not fast (nothing to eat or drink) before the test unless requested to do so by the physician.

Results

Reference values for normal levels of LDH isoenzymes vary from laboratory to laboratory but can generally be found within the following ranges:

- LDH-1: 17–27%
- LDH-2: 27–37%
- LDH-3: 18–25%
- LDH-4: 8–16%
- LDH-5: 6–16%

Increased levels of LDH-1 are seen in myocardial infarction, red blood cell diseases like **hemolytic anemia**, **kidney disease** including **kidney transplantation** rejection, and testicular tumors. Increased levels of LDH-2 are found in lung diseases such as pneumonia and congestive **heart failure**, as well as in lymphomas and other tumors. Elevations of LDH-3 are significant

KEY TERMS

Differential diagnosis—Comparing and contrasting the signs, symptoms, and laboratory findings of two or more diseases to determine which is causing the patient's condition.

Enzyme—A protein that regulates the rate of a chemical reaction in the body, increasing the speed at which the change occurs.

Isoenzyme—One of a group of enzymes that bring about the same reaction but are vary in their physical properties.

in lung disease and certain tumors. Elevations of LDH-4 are greatly increased in **pancreatitis**. High levels of LDH-5 are found in liver disease, intestinal problems, and skeletal muscle disease and injury, such as **muscular dystrophy** and recent muscular **trauma**.

Diffuse disease or injury (for example, collagen disease, **shock**, low blood pressure) and advanced solid-tumor cancers cause significant elevations of all LDH isoenzymes at the same time.

Risks

Risks for this test are minimal. The patient may experience slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after the vein is punctured (venipuncture), or an accumulation of blood under the puncture site (hematoma).

Lactate dehydrogenase test

Definition

Lactate dehydrogenase, also called lactic dehydrogenase, or LDH, is an enzyme found in the cells of many body tissues, including the heart, liver, kidneys, skeletal muscle, brain, red blood cells, and lungs. It is responsible for converting muscle lactic acid into pyruvic acid, an essential step in producing cellular energy.

Purpose

Lactic dehydrogenase is present in almost all body tissues, so the LDH test is used to detect tissue alterations and as an aid in the diagnosis of **heart attack**, anemia, and **liver disease**. Newer injury markers are becoming more useful than LDH for heart attack diagnosis.

Precautions

Because the LDH enzyme is so widely distributed throughout the body, cellular damage causes an elevation of the total serum LDH. As a result, the diagnostic usefulness of this enzyme by itself is not as valuable as determination of the five fractions that comprise the LDH. These fractions are called isoenzymes and are better indicators of disease than is the total LDH. The fractions are LDH-1, LDH-2, LDH-3, LDH-4, and LDH-5. A normal total LDH level does not mean that individual isoenzyme levels should not be measured. Individual isoenzyme ranges can help differentiate a diagnosis.

Description

When disease or injury affects tissues containing LDH, the cells release LDH into the bloodstream, where it is identified in higher than normal levels. For example, when a person has a heart attack, the LDH level begins to rise about 12 hours after the attack and usually returns to normal within 5–10 days. The LDH is also elevated in diseases of the liver, in certain types of anemia, and in cases of excessive destruction of cells, as in **fractures**, **trauma**, muscle damage, and **shock**.

Cancers can also elevate LDH level. Additionally, some patients have chronically elevated LDH with no identifiable cause and no apparent consequence.

Preparation

This test requires a blood sample. It is not necessary for the patient to fast (nothing to eat or drink) before the test unless the physician requests it.

Results

Reference ranges for total LDH vary from laboratory to laboratory. Normal values are also higher in childhood. For adults, in most laboratories, the range can be up to approximately 200 units/L, but is usually found within 45-90 U/L.

Abnormal

Due to the fact that many common disease processes cause elevations in the total LDH level, a breakdown of the five different isoenzymes that make up the

total LDH is often helpful for diagnosis. In certain disorders, the total LDH may be within normal limits, but individual isoenzyme elevations can indicate specific organ or tissue damage. For example, the LDH-2 fraction is normally greater than LDH-1 in the blood. After an acute heart attack, however, the LDH-1 rises over the LDH-2 in what is known as a "flipped LDH."

Certain diagnoses can be assisted by determination of the total LDH. One example is **infectious mononucleosis**, in which the LDH is usually more elevated than a liver enzyme called AST. Conversely, in cases of viral hepatitis, the liver enzymes AST and ALT are greatly increased over the LDH.

Risks for this test are minimal, but may include slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after venipuncture, or hematoma (blood accumulating under the puncture site).

Lactation

Definition

Lactation is the medical term used for **breastfeeding**. It also specifically refers to the synthesis and secretion of milk.

Purpose

Breastfeeding provides a baby with **nutrition** in the form of breast milk. Not only does breast milk contain all the nutrients needed by a rapidly developing newborn, but it also contains antibodies that provide the baby with additional protection from common early childhood diseases.

Precautions

Most common illnesses cannot be transmitted via breast milk. However, some viruses, including HIV (the virus that causes **AIDS**) can be passed in breast milk; for this reason, women who are HIV-positive should not breastfeed. **Vitamin D** supplements are often recommended for babies who are breastfed because breast milk is low in vitamin D, a vitamin that promotes strong bones.

Many medications have not been tested in nursing women, so it is not known if these drugs can affect a breast-fed child. A nursing woman should always check with her doctor before taking any medications, including over-the-counter drugs.

In addition, these drugs are not safe to take while nursing:

- radioactive drugs for some diagnostic tests
- chemotherapy drugs for cancer
- bromocriptine
- ergotamine
- lithium
- methotrexate
- street drugs (including marijuana, heroin, amphetamines)
- tobacco

Breastfeeding women should not drink alcohol for at least two hours before breastfeeding, and should not smoke.

Description

Early in a woman's **pregnancy** her milk-producing glands, called mammary glands, begin to prepare for the baby's arrival and by the sixteenth week of pregnancy the breasts are ready to produce milk. Shortly after the baby is born, the expulsion of the placenta triggers hormone shifts in the woman's body to activate lactation. The levels of the hormones estrogen and progesterone fall abruptly while the level of the hormone prolactin—the main hormone involved in the biosynthesis of milk—increases. The anterior pituitary gland secretes prolactin during lactation in very large quantities so that by 36–96 hours after the baby's birth the woman's milk volume has dramatically increased. After this time, the volume of milk the mother produces levels off and the removal of

milk becomes the predominant factor in regulating the volume of milk production.

Another hormone called oxytocin controls the release of milk from the breasts. The baby's sucking stimulates nerve endings in the nipple, which signal the mother's pituitary gland to release the oxytocin. This is called the "let–down reflex." While the baby's sucking is the primary stimulus for the reflex, a baby's cry, thoughts of the baby, or the sound of running water also may trigger the response.

Breast milk cannot be duplicated by artificial milk, although both contain protein, fat, and carbohydrates. Breast milk changes to meet the specific needs of a baby. In particular, the mother produces milk called colostrum at the end of pregnancy and in the initial postpartum period. Colostrum is called "first milk" and is thicker than mature milk. It is yellowish in color and is rich in proteins, many of which are immunoglobulins that can protect the child against illness and **allergies**. Immunoglobulins are part of the body's natural defense system against infections and other agents that can cause disease. Breast milk also helps a baby's own immune system mature faster. As a result, breast-fed babies have fewer ear infections, bouts of **diarrhea**, **rashes**, allergies, and other medical problems than bottle-fed babies do.

Benefits

In addition to providing some protection against infection, breast milk has other benefits. Because it is easily digested, babies are less likely to get constipated.

Breastfeeding is also good for the mother. It releases hormones that stimulate the uterus to contract, helping the uterus to return to normal size after delivery and reducing the risk of bleeding. The act of producing milk **burns** calories, which helps the mother to lose excess weight gained during pregnancy. Breastfeeding also may be related to a lower risk of **breast cancer**, **ovarian cancer**, and **cervical cancer**.

Breast milk is free, and saves money by eliminating the need to buy artificial milk (formula), bottles, and nipples. It also eliminates the need to sterilize feeding equipment and mix formula with clean, pathogen-free water, a critical consideration in many developing countries. Because breast-fed babies overall have fewer illnesses, their health care costs may be lower.

Breastfeeding should begin as soon as possible after birth and should continue every two to three hours. However, all babies are different; some need to nurse very frequently at first, while others can go much longer between feedings. A baby should be fed at least eight to 12 times in 24 hours. Because breast milk is easily digested, a baby may be hungry again as soon as one and one-half hours after the last meal. Frequent nursing will also help in increasing milk production.

Some babies have no trouble breastfeeding, while others may need some assistance. Once the baby begins to suck, the mother should make sure that most of the areola (the colored part of the nipple) is in the baby's mouth. Proper latching-on will help stimulate milk flow and will prevent nipple soreness.

Breastfeeding mothers should offer the baby both breasts at each feeding. Breastfeeding takes about 15–20 minutes on each side. After stopping the feeding on one side, the mother should burp the baby before offering the other breast. If the baby does not continue feeding, the next feeding should begin with the second breast.

Mothers can tell if the baby is getting enough milk by checking diapers; a baby who is wetting between four to six disposable diapers or six to eight cloth diapers and who has three or four bowel movements in 24 hours is probably getting enough milk.

Preparation

Loose, front-opening clothes and a good nursing bra are recommended. Mothers should find a comfortable chair with lots of pillows, supporting the arm and back, in which to nurse. Feet should rest on a low footstool with knees raised slightly. The baby should be level with the breast. The new mother may have to experiment with different ways of holding the baby before finding one that is comfortable for both the mother and baby.

Several members of the health care team, including obstetricians, nurses, midwives, and lactation consultants, are equipped to provide guidance and support to mothers who wish to breastfeed their babies. By meeting specific eligibility requirements and passing an independent examination, lactation consultants may be certified by the International Board of Lactation Consultants. Such certification demonstrates that these consultants possess the necessary skills, knowledge, and attitudes to provide quality breastfeeding assistance. It is important for new mothers to understand that breastfeeding is something that mothers and babies must learn to do together. The development of a satisfying breastfeeding relationship requires patience on the mother's part and the mother may benefit from the support and guidance of a lactation consultant or other qualified member of her health care team.

KEY TERMS

Areola—The pigmented, circular area surrounding the nipple of each breast.

Bromocriptine—A drug used to treat Parkinson's disease that can decrease a woman's milk supply.

Ergotamine—A drug used to prevent or treat migraine headaches. This can cause vomiting, diarrhea, and convulsions in infants.

Immunoglobulin—A protein produced by plasma cells; a component of the immune system. Transferred in utero and through breast milk, immunoglobulins provide passive immunity to the baby.

Lactation—Secretion of milk from the breasts; the act of breastfeeding.

Latch-on—The process whereby the baby opens the mouth widely and first exerts negative pressure on the mother's nipple and then positive pressure. Good latch-on will result in adequate transfer of milk into the baby's mouth and prevent sore nipples from occurring.

Lithium—A drug used to treat manic depression (bipolar disorder) that can be transmitted in breast milk.

Methotrexate—An anticancer drug also used to treat arthritis that can suppress an infant's immune system when taken by a nursing mother.

Postpartum—Refers to the six-week period after childbirth.

Risks

New mothers may experience **breastfeeding problems**, including:

- Engorged breasts. Breasts that are too full can prevent the baby from sucking. Expressing milk manually or with a breast pump can help, as can warm showers and compresses.
- Sore nipples. In the early weeks nipples may become sore and even cracked. Treatments include changing the position that the baby nurses in, ensuring that the baby has latched on to most of the areola, and using lanolin-based lotion on the nipples. Nipple shields are sometimes effective as a short-term remedy, but their use may reduce milk supply, further irritate the breast, and change the baby's sucking pattern.
- Inverted nipples: A mother with inverted nipples may still breastfeed in most instances. The baby should be enticed to open the mouth widely before latching on. The mother can use various techniques to evert the nipple such as wearing a breast shell between feedings, rolling the nipple, pulling the nipple out, and applying a breast pump on the breast for a few seconds before starting the breastfeeding session.
- Infection. Soreness and inflammation on the breast surface or a fever in the mother, may be an indication of a breast infection called mastitis. Antibiotics and continued nursing on the affected side may solve the problem.

Results

There are no rules about when to stop breastfeeding. A baby needs breast milk or artificial milk for at least the first year of life. As long as a baby eats age-appropriate solid food, the mother may nurse for several years.

Several members of the healthcare team, including obstetricians, nurses, midwives, and lactation consultants, are equipped to provide guidance and support to mothers who wish to breastfeed their babies. By meeting specific eligibility requirements and passing an independent examination, lactation consultants may be certified by the International Board of Lactation Consultants. Such certification demonstrates that these consultants possess the necessary skills, knowledge, and attitudes to provide quality breastfeeding assistance. It is important for new mothers to understand that breastfeeding is something that mothers and babies must learn to do together. The development of a satisfying breastfeeding relationship requires patience on the mother's part and the mother may benefit from the support and guidance of a lactation consultant or other qualified member of her healthcare team.

Lactic acid test

Definition

Lactic acid is an acid produced by cells during chemical processes in the body that do not require oxygen (anaerobic metabolism). Anaerobic metabolism occurs only when too little oxygen is present for the more usual aerobic metabolism (oxygen requiring). Lactic acid is a contributing factor in **muscle cramps**. It is also produced in tissues when conditions such as **heart attack** or **shock** reduce the blood supply responsible for carrying oxygen. Normally, lactic acid is removed from the blood by the liver. When an excess of lactic acid accumulates for any reason, the result is a condition called lactic acidosis.

Purpose

The lactic acid test is used as an indirect assessment of the oxygen level in tissues and to determine the cause and course of lactic acidosis.

Precautions

During blood collection, the patient should be instructed to relax the hand. Clenching and unclenching the fist will cause a build-up of potassium and lactic acid from the hand muscles that will falsely elevate the levels.

Description

The degree of acidity is an important chemical property of blood and other body fluids. Acidity is expressed on a pH scale where 7.0 is neutral, above 7.0 is basic (alkaline), and below 7.0 is acidic. A strong acid has a very low pH (near 1.0). A strong base has a very high pH (near 14.0). Blood is normally slightly alkaline or basic. It has a pH range of 7.35–7.45. The balance of acid to base in blood is precisely controlled. Even a minor deviation from the normal range can severely affect many organs.

Lactic acid (present in the blood as lactate ion) is a product of the breakdown of glucose to generate energy. It is found primarily in muscle cells and red blood cells. The lactate ion concentration in the blood depends on the rates of energy production and metabolism. Levels may increase significantly during **exercise**.

Together, lactic acid and another chemical (pyruvate) form a reversible reaction regulated by the oxygen supply to the blood and tissues. When oxygen levels are low, pyruvate converts to lactic acid; when oxygen levels are adequate, lactic acid converts to pyruvate. When the liver fails to metabolize lactose sufficiently or when too much pyruvate converts to lactate, lactic acidosis occurs. Measurement of blood lactate levels is recommended for all patients with symptoms of lactic acidosis. Testing is generally indicated if the blood pH level falls below 7.25–7.35.

Because of the close relationship between pyruvate and lactic acid, comparison of blood levels of the two substances can provide reliable information about tissue oxidation. However, pyruvate measurement is technically difficult and seldom performed. Lactic acid is measured more often, in either venous or arterial blood samples.

Preparation

This test requires a blood sample. The patient should have nothing to eat or drink (fasting) from midnight the night before the test. Because lactic acid is produced by exertion, the patient should rest for at least one hour before the test.

Results

Reference values vary from laboratory to laboratory but can be found within the following ranges:

- Venous blood: 4.5–19.8 mg/dL
- Arterial blood: 4.5–14.4 mg/dL

KEY TERMS

Acidosis—A disturbance of the balance of acid to base in the body causing an accumulation of acid or loss of alkali (base). There are two types of acidosis: metabolic and respiratory. One of the most common causes of metabolic acidosis is an overdose of aspirin. Respiratory acidosis is caused by impaired breathing caused by conditions such as severe chronic bronchitis, bronchial asthma, or airway obstruction.

High blood lactate levels, together with decreased oxygen in tissues, may be caused by strenuous muscle exercise, shock, hemorrhage, severe infection in the blood stream, heart attack, or cardiac arrest. When tissue oxygenation is low for no apparent reason, increased lactate levels may be caused by systemic disorders like diabetes, leukemia, **liver disease**, or kidney failure. Defects in enzymes may also be responsible, as in glycogen storage disease (von Gierke's disease). Lactate is also increased in certain instances of intestinal obstruction.

Lactic acidosis can be caused by taking large doses of **acetaminophen** and alcohol and by intravenous infusion of epinephrine, glucagon, fructose, or sorbitol. Antifreeze **poisoning** can also cause lactic acidosis. In rare instances, a diabetic medication, metformin (Glucophage), causes lactic acidosis. People with weak kidneys should not take metformin.

Risks

Risks for this test are minimal. The patient may experience slight bleeding from the blood-drawing site, **fainting** or feeling lightheaded after puncture of the vein (venipuncture), or an accumulation of blood under the puncture site (hematoma).

Lactose intolerance

Definition

Lactose intolerance refers to the inability of the body to fully digest lactose, which is a type of sugar found in milk. It is also sometimes called lactose deficiency. Although the condition is neither serious nor fatal, it can cause much discomfort in the form of gastrointestinal distress. Many people have low levels of the enzyme lactase in their bodies (which break down lactose) but do not show any symptoms of lactose intolerance. Thus, people with lactose intolerance have both low lactase levels and the associated symptoms. The condition can be regulated by reducing or eliminating the consumption of products containing milk.

Demographics

The condition of being lactose intolerant is common in adults around the world. However, it is more common in such ethnic groups as Africans, African Americans, South Americans, Asians, Native Americans, and people from Mediterranean descent. It is less common in people descended from, or living in, northern and western parts of Europe and North America. The age at which lactose intolerance first begins can vary. In Caucasians, the first signs of lactose intolerance can begin as early as the age of five years. In African Americans, the age is even earlier, at two years. An estimated 30 million American adults (out of about 220 million adults, in 2010, about 14%) have some degree of lactose intolerance by the age of 20 years.

Description

Lactose is the form of sugar present in milk and other dairy products, and some non-dairy products, too. Human milk is considered the product with the highest concentration of lactose, with about 9%. Unprocessed cow milk has about 4.7% of lactose. The enzyme lactase, which is normally produced by cells lining the small intestine, breaks down lactose into substances that can be absorbed into the bloodstream. When dairy products are ingested, the lactose reaches the digestive system and is broken down by lactase into the simpler sugars of glucose and galactose. The liver changes the galactose into glucose, which then enters the bloodstream and raises the blood glucose level. Lactose intolerance occurs when, due to a deficiency of lactase, lactose is not completely broken down, unprocessed lactose proceeds into the colon (large intestine), and the glucose level does not

rise. While not usually dangerous, lactose intolerance can cause severe discomfort in the form of bloating, **diarrhea**, and gas.

It is estimated that from 30 to 50 million Americans, young and old, suffer from the symptoms of lactose intolerance, but not everyone who is deficient in lactase experiences symptoms. Experts contend that approximately 75% of the adult population worldwide does not produce enough lactase and is at risk for some or all of the symptoms of lactose intolerance.

Risk factors

Many factors may cause increasing risk of contracting lactose intolerance. Some of these major factors include:

- Ethnicity (certain ethnic groups are more predisposed to it)
- Age (as one ages the condition becomes more common)
- Diseases (especially relating to the small intestines, such as Celiac disease and Crohn's disease)
- Premature babies (reduced levels of lactase are common in infants born prematurely)
- Radiation (directed toward the abdominal area).

Causes and symptoms

Lactose intolerance can be caused by some diseases of the digestive system and by injuries to the small intestine that result in a decreased production of lactase. This type of the condition is called secondary lactose intolerance. While rare, some children are also born unable to produce the enzyme. This type is called congenital lactose intolerance, being passed down from both parents to the child through autosomal recessive inheritance. For many, however, lactase deficiency develops naturally because, after about two years of age, the body produces less lactase. When age is a factor in acquiring the condition, it is called primary lactose intolerance.

Overall, symptoms include nausea, cramps, diarrhea, abdominal bloating, gas (flatulence), floating and foul-smelling stools, **malnutrition**, and weight loss. In children, an additional symptom is slow growth. The symptoms, which may be mild to severe, usually occur between 30 minutes to two hours after eating or drinking lactose-containing foods.

Diagnosis

Usually health care professionals measure the absorption of lactose in the digestive system by using the lactose tolerance test, lactose-hydrogen breath test, or stool acidity test. Each of these can be performed outpatient, through a hospital, clinic or doctor's office.

People taking the lactose tolerance test must fast before being tested. They then drink a lactose-containing liquid for the test and medical personnel take blood samples during the next two hours to measure the patient's blood glucose level. The blood glucose level, or blood sugar level, indicates how well the body is digesting the lactose. A diagnosis of lactose intolerance is confirmed when blood glucose level does not rise. This test is not administered to infants and very young children because they are more prone to **dehydration**, which can result from diarrhea from the liquid.

Health care professionals measure the amount of hydrogen in the breath using the lactose-hydrogen breath test. Hydrogen is usually detected only in small amounts in the breath. However, when bacteria ferment undigested lactose, which is found in the colon, hydrogen in the breath is produced in greater quantities. The hydrogen is exhaled after being absorbed from the intestines and carried through the bloodstream to the lungs. The hydrogen breath test involves having the patient drink a lactose-containing beverage. Health care professionals monitor the breath at regular intervals to see if the hydrogen levels rise, which indicates improper lactose digestion. People taking the test who have had certain foods, medications, or cigarettes before the test may get inaccurate results. While the test is available to children and adults, newborns and young children should not have it because of the risk of dehydration from drinking the beverage that can cause diarrhea in those who are lactose intolerant.

A stool acidity test measures the amount of acid in the stool. This is a safe test for newborns and young children. The test detects lactic acid and other short-chain fatty acids from undigested lactose fermented by bacteria in the colon. Glucose might also be in the stool sample, resulting form unabsorbed lactose in the colon.

Medical professionals may also examine the small intestines with a procedure called an enteroscopy. A thin, flexible tube, which is called an endoscope, is inserted through the mouth or nose and down into the upper gastrointestinal tract. Balloons, attached to the endoscope, allow the physician the ability to observe the small intestine. A procedure called a **colonoscopy** may also be used. A tube is inserted into the rectum and up into the small intestine. In both cases, tissue samples may be removed and examined by trained laboratory technicians.

WWW.BOOKBAZ.IR

Treatment

Pediatricians might recommend that parents of newborns and very young children who are suspected of having lactose intolerance simply change from cow's milk to a soy formula. Since treatments are not available that can improve the body's ability to produce lactase, lactose deficiency treatments instead, are focused on controlling the diet.

Most people affected by lactose intolerance do well if they limit their intake of lactose foods and drinks. People differ in the amounts they can handle before experiencing symptoms. Some have to stop lactose completely. People who are sensitive after ingesting small amounts of lactose can take lactase enzymes, which are available without a prescription. Using the liquid form, people can add a few drops in their milk, put the milk in the refrigerator and drink it after 24 hours, when the lactase enzymes have worked to reduce the lactose content by 70%. If the milk is heated first and double the amount of lactase liquid is added, the milk will be 90% lactose free. Recently, researchers have developed a chewable lactase enzyme tablet. By taking three to six tablets just before eating, the tablets help people digest lactose-containing solid foods. Supermarkets also carry lactose-reduced milk and other products, which contain the needed nutrients found in the regular products but without the lactose.

Foods that contain lactose are milk, low-fat milk, skim milk, chocolate milk, buttermilk, sweetened condensed milk, dried whole milk, instant nonfat dry milk, low-fat yogurts, frozen yogurts ice cream, ice milk, sherbet, cheese, cottage cheese, low-fat cottage cheese, cream and butter. Other foods that may contain hidden lactose are: nondairy creamers, powdered artificial sweeteners, foods containing milk power or nonfat milk solids, bread, cake, margarine, creamed soups, pancakes, waffles, processed breakfast cereals, salad dressings, luncheon meats, potato chips, puddings, custards, confections and some meat products. These forms of hidden lactose may appear on packaging labels as whey, curds, milk solids, lactoserum, dry milk solids, milk by-products, modified milk ingredients, non-fat dry milk powder, and other such terms.

Many cultured milk products, such as yogurt, contain **probiotics**, which are living organisms that help to maintain a well regulated digestive system. These products can be used to help with gastrointestinal problems. Probiotics also help to digest lactose, when the body cannot do so naturally.

Prognosis

Lactose intolerance is easy to manage. People of all ages however, especially children, have to replace the **calcium** lost during the reduction (or elimination) of milk products by taking supplements and eating calcium-rich foods, such as leafy vegetables (broccoli, spinach, and kale), certain seafood (canned salmon, oysters, sardines, and shrimp), calcium-fortified foods, almonds, oranges, pinto beans, rhubarb, and tofu. Many people who suffer with lactose intolerance will be able to continue eating some milk products. Some diary products may be tolerable to one's system depending on the amount of lactose contained within t hem. Many times milk can be consumed in smaller amounts to lessen the problem associated with the malady. In addition, milk consumed with meals is usually less problematic. Yogurt contains enzymes that break down lactose, so lactose-intolerant people may tolerate it. The condition is not considered dangerous. However, unless treated properly, people with lactose intolerance have to contend with weight loss and malnutrition, along with many symptoms that cause discomfort.

KEY TERMS

Galactose—Simple sugar derived from milk sugar.

Glucose—A simple sugar and the chief energy source in the body.

Lactase enzyme—The enzyme produced by cells that line the small intestine which allows the body to break down lactose.

Lactose—The primary sugar in milk.

Prevention

Often, lactose intolerance is a natural occurrence that cannot be avoided. However, people can prevent symptoms by managing the condition with diet and lactase supplements. Foods and beverages that state they are "lactose-free" can be substituted for diary products. Milk can be treated with commercially available lactase products (lactase drops) that remove almost all of the lactose contained within milk. Lactase capsules or tablets are also available, which can be taken orally before eating meals that include dairy products.

Laminectomy

Definition

A laminectomy is a surgical procedure in which the surgeon removes a portion of the bony arch, or lamina, on the dorsal surface of a vertebra, which is one of the bones that make up the human spinal column. It is done to relieve back **pain** that has not been helped by more conservative treatments. In most cases a laminectomy is an elective procedure rather than emergency surgery. A laminectomy for relief of pain in the lower back is called a lumbar laminectomy or an open decompression.

Purpose

Structure of the spine

In order to understand why removal of a piece of bone from the arch of a vertebra relieves pain, it is helpful to have a brief description of the structure of the spinal column and the vertebrae themselves. In humans, the spine comprises 33 vertebrae, some of which are fused together. There are seven vertebrae in the cervical (neck) part of the spine; 12 vertebrae in the thoracic (chest) region; five in the lumbar (lower back) region; five vertebrae that are fused to form the sacrum; and four vertebrae that are fused to form the coccyx, or tailbone. It is the vertebrae in the lumbar portion of the spine that are most likely to be affected by the disorders that cause back pain.

The 24 vertebrae that are not fused are stacked vertically in an S-shaped column that extends from the tailbone below the waist up to the back of the head. This column is held in alignment by ligaments, cartilage, and muscles. About half the weight of a person's body is carried by the spinal column itself and the other half by the muscles and ligaments that hold the spine in alignment. The bony arches of the laminae on each vertebra form a canal that contains and protects the spinal cord. The spinal cord extends from the base of the brain to the upper part of the lumbar spine, where it ends in a collection of nerve fibers known as the cauda equina, which is a Latin phrase meaning "horse's tail." Other nerves branching out from the spinal cord pass through openings formed by adjoining vertebrae. These openings are known as foramina (singular, foramen).

Between each vertebra is a disk that serves to cushion the vertebrae when a person bends, stretches, or twists the spinal column. The disks also keep the foramina between the vertebrae open so that the spinal nerves can pass through without being pinched or damaged. As people age, the intervertebral disks begin to lose moisture and break down, which reduces the size of the foramina between the vertebrae. In addition, bone spurs may form inside the vertebrae and cause the spinal canal itself to become narrower. Either of these processes can compress the spinal nerves, leading to pain, tingling sensations, or weakness in the lower back and legs. A lumbar laminectomy relieves pressure on the spinal nerves by removing the disk, piece of bone, tumor, or other structure that is causing the compression.

Causes of lower back pain

The disks and vertebrae in the lower back are particularly vulnerable to the effects of **aging** and daily wear and tear because they bear the full weight of the upper body, even when one is sitting quietly in a chair. When a person bends forward, 50% of the motion occurs at the hips, but the remaining 50% involves the lumbar spine. The force exerted in

In this posterior (from the back) lumbar laminectomy, an incision is made in the patient's back over the lumbar vertebrae (A). The wound is opened with retractors to expose the L2 and L3 vertebrae (B). bending is not evenly divided among the five lumbar vertebrae; the segments between the third and fourth lumbar vertebrae (L3-L4) and the fourth and fifth (L4-L5) are most likely to break down over time. More than 95% of spinal disk operations are performed on the fourth and fifth lumbar vertebrae.

KEY TERMS

Cauda equina—The collection of spinal nerve roots that lie inside the spinal column below the end of the spinal cord. The name comes from the Latin for "horse's tail."

Cauda equina syndrome (CES)—A group of symptoms characterized by numbness or pain in the legs and/or loss of bladder and bowel control, caused by compression and paralysis of the nerve roots in the cauda equina. CES is a medical emergency.

Chiropractic—A system of therapy based on the notion that health and disease are related to the interactions between the brain and the nervous system. Treatment involves manipulation and adjustment of the segments of the spinal column. Chiropractic is considered a form of alternative medicine.

Decompression—Any surgical procedure done to relieve pressure on a nerve or other part of the body. A laminectomy is sometimes called an open decompression.

Dorsal—Referring to a position closer to the back than to the stomach. The laminae in the spinal column are located on the dorsal side of each vertebra.

Dura—A tough fibrous membrane that covers and protects the spinal cord.

Foramen (plural, foramina)—The medical term for a natural opening or passage. The foramina of the spinal column are openings between the vertebrae for the spinal nerves to branch off from the spinal cord.

Laminae (singular, lamina)—The broad plates of bone on the upper surface of the vertebrae that fuse together at the midline to form a bony covering over the spinal canal.

Laminotomy—A less invasive alternative to a laminectomy in which a hole is drilled through the lamina.

Ligamenta flava (singular, ligamentum flavum)—A series of bands of tissue that are attached to the vertebrae in the spinal column. They help to hold the spine straight and to close the spaces between the laminar arches. The Latin name means "yellow band(s)."

Lumbar—Pertaining to the part of the back between the chest and the pelvis.

Myelogram—A special type of x-ray study of the spinal cord, made after a contrast medium has been injected into the space surrounding the cord.

Osteopathy—A system of therapy that uses standard medical and surgical methods of diagnosis and treatment while emphasizing the importance of proper body alignment and manipulative treatment of musculoskeletal disorders. Osteopathy is considered mainstream primary care medicine rather than an alternative system.

Pain disorder—A psychiatric disorder in which pain in one or more parts of the body is caused or made worse by psychological factors. The lower back is one of the most common sites for pain related to this disorder.

Retractor—An instrument used during surgery to hold an incision open and pull back underlying layers of tissue.

Sciatica—Pain in the lower back, buttock, or leg along the course of the sciatic nerve.

Somatization disorder—A chronic condition in which psychological stresses are converted into physical symptoms that interfere with work and relationships. Lower back pain is a frequent complaint of patients with somatization disorder.

Spinal stenosis—Narrowing of the canals in the vertebrae or around the nerve roots, causing pressure on the spinal cord and nerves.

Vertebra (plural, vertebrae)—One of the bones of the spinal column. There are 33 vertebrae in the human spine.

Specific symptoms and disorders that affect the lower back include:

- Sciatica. Sciatica refers to sudden pain felt as radiating from the lower back through the buttocks and down the back of one leg. The pain, which may be experienced as weakness in the leg, a tingling feeling, or a "pins and needles" sensation, runs along the course of the sciatic nerve. Sciatica is a common symptom of a herniated disk.
- Spinal stenosis. Spinal stenosis is a disorder that results from the narrowing of the spinal canal surrounding the spinal cord and eventually compressing the cord. It may result from hereditary factors, from the effects of aging, or from changes in the pattern of blood flow to the lower back. Spinal stenosis is sometimes difficult to diagnose because its early symptoms can be caused by a number of other conditions and because the patient usually has no history

WWW.BOOKBAZ.IR

of back problems or recent injuries. Imaging studies may be necessary for accurate diagnosis.

- Cauda equina syndrome (CES). Cauda equina syndrome is a rare disorder caused when a ruptured disk, bone fracture, or spinal stenosis put intense pressure on the cauda equina, the collection of spinal nerve roots at the lower end of the spinal cord. CES may be triggered by a fall, automobile accident, or penetrating gunshot injury. It is characterized by loss of sensation or altered sensation in the legs, buttocks, or feet; pain, numbness, or weakness in one or both legs; difficulty walking; or loss of control over bladder and bowel functions. *Cauda equina syndrome is a medical emergency requiring immediate treatment*. If the pressure on the nerves in the cauda equina is not relieved quickly, permanent paralysis and loss of bladder or bowel control may result.
- Herniated disk. The disks between the vertebrae in the spine consist of a fibrous outer part called the annulus and a softer inner nucleus. A disk is said to herniate when the nucleus ruptures and is forced through the outer annulus into the spaces between the vertebrae. The material that is forced out may put pressure on the nerve roots or compress the spinal cord itself. In other cases, the chemicals leaking from the ruptured nucleus may irritate or inflame the spinal nerves. More than 80% of herniated disks affect the spinal nerves associated with the L5 vertebra or the first sacral vertebra.
- Osteoarthritis (OA). OA is a disorder in which the cartilage in the hips, knees, and other joints gradually breaks down, allowing the surfaces of the bones to rub directly against each other. In the spine, OA may result in thickening of the ligaments surrounding the spinal column. As the ligaments increase in size, they may begin to compress the spinal cord.

Factors that increase a person's risk of developing pain in the lower back include:

- Hereditary factors. Some people are born with relatively narrow spinal canals and may develop spinal stenosis fairly early in life.
- Sex. Men are at greater risk of lower back problems than women, in part because they carry a greater proportion of their total body weight in the upper body.
- Age. The intervertebral disks tend to lose their moisture content and become thinner as people get older.
- Occupation. Jobs that require long periods of driving (long-distance trucking; bus, taxi, or limousine operation) are hard on the lower back because of vibrations from the road surface transmitted upward to the spine. Occupations that require heavy lifting (nursing, child care, construction work, airplane maintenance) put extra stress on the lumbar vertebrae. Other high-risk occupations include professional sports, professional dance, assembly line work, foundry work, mining, and mail or package delivery.
- Lifestyle. Wearing high-heeled shoes, carrying heavy briefcases or shoulder bags on one side of the body, or sitting for long periods of time in one position can all throw the spine out of alignment.
- Obesity. Being overweight, particularly if the extra pounds are concentrated in the abdomen, adds to the strain on the muscles and ligaments that support the spinal column.
- Trauma. Injuries to the back from contact sports, falls, criminal assaults, or automobile accidents may lead to misalignment of the vertebrae or a ruptured disk. Traumatic injuries may also trigger the onset of cauda equina syndrome.

Demographics

Pain in the lower back is a chronic condition that has been treated in various ways from the beginnings of human medical practice. The earliest description of disorders affecting the lumbar vertebrae was written in 3000 B.C. by an ancient Egyptian surgeon. In the modern world, back pain is responsible for more time lost from work than any other cause except the **common cold**. Between 10% and 15% of workers' compensation claims are related to chronic pain in the lower back. It is estimated that the direct and indirect costs of back pain to the American economy range between $75 and $80 billion per year.

In the United States, about 13 million people seek medical help each year for the condition. According to the Centers for Disease Control, 14% of all new visits to primary care doctors are related to problems in the lower back. The CDC estimates that 2.4 million adults in the United States are chronically disabled by back pain, with another 2.4 million temporarily disabled. About 80% of people will experience pain in the lower back at some point in their lifetime; on a yearly basis, one person in every five will have some kind of back pain.

Back pain primarily affects the adult population, most commonly people between the ages of 45 and 64. It is more common among men than women, and more common among Caucasians and Hispanics than among African Americans or Asian Americans.

Description

A laminectomy is performed with the patient under general **anesthesia**, usually positioned lying on

the side or stomach. The surgeon begins by making a small straight incision over the damaged vertebra.

The surgeon next uses a retractor to spread apart the muscles and fatty tissue overlying the spine. When the laminae have been reached, the surgeon cuts away part of the bony arch in order to expose the ligamentum flavum, which is a band of yellow tissue attached to the vertebra that helps to support the spinal column and closes in the spaces between the vertebral arches. The surgeon then cuts an opening in the ligamentum flavum in order to reach the spinal canal and expose the compressed nerve. At this point the cause of the compression (**herniated disk**, tumor, bone spur, or a fragment of the disk that has separated from the remainder) will be visible.

Bone spurs, if any, are removed in order to enlarge the foramina and the spinal canal. If the disk is herniated, the surgeon uses the retractor to move the compressed nerve aside and removes as much of the disk as necessary to relieve pressure on the nerve. The space that was occupied by the disk will be filled eventually by new connective tissue.

If necessary, a **spinal fusion** is performed to stabilize the patient's lower back. A small piece of bone taken from the hip is grafted onto the spine and attached with metal screws or plates to support the lumbar vertebrae.

Following completion of the spinal fusion, the surgeon closes the incision in layers, using different types of sutures for the muscles, connective tissues, and skin. The entire procedure takes one to three hours.

Preparation

Diagnosis

The differential diagnosis of lower back pain is complicated by the number of possible causes and the patient's reaction to the discomfort. In many cases the patient's perception of back pain is influenced by poor-quality sleep or emotional issues related to occupation or family matters. A primary care doctor will begin by taking a careful medical and occupational history, asking about the onset of the pain as well as its location and other characteristics. Back pain associated with the lumbar spine very often affects the patient's ability to move, and the muscles overlying the affected vertebrae may feel sore or tight. Pain resulting from heavy lifting usually begins within 24 hours of the overexertion. Most patients who do not have a history of chronic pain in the lower back feel better after 48 hours of bed rest with pain medication and either a heating pad or ice pack to relax **muscle spasms**.

If the patient's pain is not helped by rest and other conservative treatments, he or she will be referred to an orthopedic surgeon for a more detailed evaluation. An orthopedic evaluation includes a **physical examination**, neurological workup, and imaging studies. In the physical examination, the doctor will ask the patient to sit, stand, or walk in order to see how these functions are affected by the pain. The patient may be asked to **cough** or to lie on a table and lift each leg in turn without bending the knee, as these maneuvers can help to diagnose nerve root disorders. The doctor will also palpate (feel) the patient's spinal column and the overlying muscles and ligaments to determine the external location of any tender spots, **bruises**, thickening of the ligaments, or other structural abnormalities. The neurological workup will focus on the patient's reflexes and the spinal nerves that affect the functioning of the legs. Imaging studies for lower back pain typically include an x-ray study and CT scan of the lower spine, which will reveal bone deformities, narrowing of the intervertebral disks, and loss of cartilage. An MRI may be ordered if **spinal stenosis** is suspected. In some cases the doctor may order a myelogram, which is an x ray or CT scan of the lumbar spine performed after a special dye has been injected into the spinal fluid.

Lower back pain is one of several common general medical conditions that require the doctor to assess the possibility that the patient has a concurrent psychiatric disorder. Such diagnoses as somatization disorder or pain disorder do not mean that the patient's physical symptoms are imaginary or that they should not receive surgical or medical treatment. Rather, a psychiatric diagnosis indicates that the patient is allowing the back pain to become the central focus of life or responding to it in other problematic ways. Some researchers in Europe as well as North America think that the frequency of lower back problems in workers' disability claims reflect emotional dissatisfaction with work as well as physical stresses related to specific jobs.

Preparation

Most hospitals require patients to have the following tests before a laminectomy: a complete physical examination; **complete blood count** (CBC); an electrocardiogram (EKG); a urine test; and tests that measure the speed of blood clotting.

Aspirin and arthritis medications should be discontinued seven to 10 days before a laminectomy

WWW.BOOKBAZ.IR

because they thin the blood and affect clotting time. Patients should provide the surgeon and anesthesiologist with a complete list of all medications, including over-the-counter and herbal preparations, that they take on a regular basis.

The patient is asked to stop **smoking** at least a week before surgery and to take nothing by mouth after midnight before the procedure.

Aftercare

Aftercare following a laminectomy begins in the hospital. Most patients will remain in the hospital for one to three days after the procedure. During this period the patient will be given fluids and antibiotic medications intravenously to prevent infection. Medications for pain will be given every three to four hours, or through a device known as a PCA (patient-controlled anesthesia). The PCA is a small pump that delivers a dose of medication into the IV when the patient pushes a button. To get the lungs back to normal functioning, a respiratory therapist will ask the patient to do some simple breathing exercises and begin walking within several hours of surgery.

Aftercare during the hospital stay is also intended to lower the risk of a venous thromboembolism (VTE), or blood clot in the deep veins of the leg. Prevention of VTE involves medications to thin the blood and wearing compression stockings or boots.

Most surgeons prefer to see patients one week after surgery to remove stitches and check for any postoperative complications. Patients should not drive or return to work before their checkup. A second follow-up examination is usually done four to eight weeks after the laminectomy.

Patients can help speed their recovery by taking short walks on a daily basis; avoiding sitting or standing in the same position for long periods of time; taking brief naps during the day; and sleeping on the stomach or the side. They may take a daily bath or shower without needing to cover the incision. The incision should be carefully patted dry, however, rather than rubbed.

Results

Normal results depend on the cause of the patient's lower back pain; most patients can expect considerable relief from pain and some improvement in functioning. There is some disagreement among surgeons about the success rate of laminectomies, however, which appears to be due to the fact that the operation is generally done to improve quality of life—cauda equina syndrome is the only indication for an emergency laminectomy. Different sources report success rates between 26% and 99%, with 64% as the average figure. According to one study, 31% of patients were dissatisfied with the results of the operation, possibly because they may have had unrealistic expectations of the results.

Morbidity and mortality rates

The mortality rate for a lumbar laminectomy is between 0.8% and 1%. Rates of complications depend partly on whether a spinal fusion is performed as part of the procedure; while the general rate of complications following a lumbar laminectomy is given as 6–7%, the rate rises to 12% of a spinal fusion has been done.

Risks

Risks associated with a laminectomy include:

- bleeding
- infection
- damage to the spinal cord or other nerves
- weakening or loss of function in the legs
- blood clots
- leakage of spinal fluid resulting from tears in the dura, the protective membrane that covers the spinal cord
- worsening of back pain

Alternatives

Conservative treatments

Surgery for lower back pain is considered a treatment of last resort, with the exception of cauda equina syndrome. Patients should always try one or more conservative approaches before consulting a surgeon about a laminectomy. In addition, most health insurers will require proof that the surgery is necessary, since the average total cost of a lumbar laminectomy is $85,000.

Some conservative approaches that have been found to relieve lower back pain include:

- Analgesic or muscle relaxant medications. Analgesics are drugs given to relieve pain. The most commonly prescribed pain medications are aspirin or NSAIDs. Muscle relaxants include methocarbamol, cyclobenzaprine, or diazepam.
- Epidural injections. Epidural injections are given directly into the space surrounding the spinal cord. Corticosteroids are the medications most commonly given by this route, but preliminary reports indicate that epidural injections of indomethacin are also effective in relieving recurrent pain in the lower back.

- Rest. Bed rest for 48 hours usually relieves acute lower back pain resulting from muscle strain.
- Appropriate exercise. Brief walks are recommended as a good form of exercise to improve blood circulation, particularly after surgery. In addition, there are several simple exercises that can be done at home to strengthen the muscles of the lower back. A short pamphlet entitled *Back Pain Exercises* may be downloaded free of charge from the American Academy of Orthopaedic Surgeons (AAOS) web site.
- Losing weight. People who are severely obese may wish to consider weight reduction surgery to reduce the stress on their spine as well as their heart and respiratory system.
- Occupational modifications or change. Lower back pain related to the patient's occupation can sometimes be eased by taking periodic breaks from sitting in one position; by using a desk and chair proportioned to one's height; by learning to use the muscles of the thighs when lifting heavy objects rather than the lower back muscles; and by maintaining proper posture when standing or sitting. In some cases the patient may be helped by changing occupations.
- Physical therapy. A licensed physical therapist can be helpful in identifying the patient's functional back problems and planning a course of treatment to improve flexibility, strength, and range of motion.
- Osteopathic manipulative treatment (OMT). Osteopathic physicians (DOs) receive the same training in medicine and surgery as MDs; however, they are also trained to evaluate postural and spinal abnormalities and to perform several different manual techniques for relief of back pain. An article published in the *New England Journal of Medicine* in 1999 reported that OMT was as effective as physical therapy and standard medication in relieving lower back pain, with fewer side effects and lower health care costs. OMT is recommended in the United Kingdom as a very low-risk treatment that is more effective than bed rest or mild analgesics.
- Transcutaneous electrical nerve stimulation (TENS). TENS is a treatment technique developed in the late 1960s that delivers a mild electrical current to stimulate nerves through electrodes attached to the skin overlying a painful part of the body. It is thought that TENS works by stimulating the production of endorphins, which are the body's natural painkilling compounds.

Surgical alternatives

The most common surgical alternative to laminectomy is a minimally invasive laminotomy and/or microdiscectomy. In this procedure, which takes about an hour, the surgeon makes a 0.5 in (1.3 cm) incision in the lower back and uses a series of small dilators to separate the layers of muscle and fatty tissue over the spine rather than cutting through them with a scalpel. A tube-shaped retractor is inserted to expose the part of the lamina over the nerve root. The surgeon then uses a power drill to make a small hole in the lamina to expose the nerve itself. After the nerve has been moved aside with the retractor, a small grasping device is used to remove the herniated portion or fragments of the damaged spinal disk.

The advantages of these minimally invasive procedures are fewer complications and a shortened recovery time for the patient. The average postoperative stay is three hours. In addition, 90% of patients are pleased with the results.

Complementary and alternative (CAM) approaches

Two alternative methods of treating back disorders that have been shown to help many patients are **acupuncture** and **chiropractic**. Chiropractic is based on the belief that the body has abilities to heal itself provided that nerve impulses can move freely between the brain and the rest of the body. Chiropractors manipulate the segments of the spine in order to bring them into proper alignment and restore the nervous system to proper functioning. Many are qualified to perform acupuncture as well as chiropractic adjustments of the vertebrae and other joints. Several British and Swedish studies have reported that acupuncture and chiropractic are at least as effective as other conservative measures in relieving pain in the lower back.

Movement therapies, including **yoga**, tai chi, and gentle stretching exercises, may be useful in maintaining or improving flexibility and range of motion in the spine. A qualified yoga instructor can work with the patient's doctor before or after surgery to put together an individualized set of beneficial stretching and breathing exercises. The **Alexander technique** is a type of **movement therapy** that is often helpful to patients who need to improve their posture.

Laparoscopy

Definition

Laparoscopy, sometimes also called laparoscopic (LAP) surgery, is a minimally invasive procedure that uses a thin, lighted tube (laparoscope) to visualize internal organs. Laparoscopy is most commonly used during surgery on the abdominal and pelvic organs but may also be used for surgery of the thoracic cavity, head, or neck. In addition, tissue samples can be collected for biopsy using laparoscopy, and malignancies may be treated using laparoscopic techniques combined with other therapies. The procedure is often much less stressful for patients and on the body than procedures used in other minor or open surgeries. In addition, laparoscopy can usually be performed without the need to stay overnight in a hospital.

Purpose

Laparoscopy is performed to examine the abdominal and pelvic organs to diagnose certain conditions and can also be used to perform surgery. Laparoscopy is commonly used in gynecology to examine the outside of the uterus, the fallopian tubes, and the ovaries—particularly in pelvic **pain** cases where the underlying cause cannot be determined using diagnostic imaging (**ultrasound** and computed tomography). Examples of gynecologic conditions diagnosed using laparoscopy include **endometriosis**, **ectopic pregnancy**, **ovarian cysts**, **pelvic inflammatory disease** (PID), **infertility**, and cancer. Laparoscopy is used in **general surgery** to examine the abdominal organs,

This surgeon is performing a laparoscopic procedure on a patient. *(Photo Researchers, Inc.)*

including the gallbladder, bile ducts, liver, appendix, and intestines.

During a laparoscopic procedure, certain conditions can be treated using instruments and devices specifically designed for laparoscopy. Medical devices that can be used in conjunction with laparoscopy include surgical lasers and electrosurgical units. Laparoscopic surgery is now preferred over open surgery for several types of procedures because it is minimally invasive associated with fewer complications.

Microlaparoscopy can be performed in the physician's office using smaller laparoscopes. Common clinical applications in gynecology include pain mapping (for endometriosis), sterilization, and fertility procedures. Common applications in general surgery include evaluation of chronic and acute abdominal pain (as in **appendicitis**), basic **trauma** evaluation, biopsies, and evaluation of abdominal masses. Laparoscopy may also be used to find problems such as **adhesions**, cysts, and infections.

Laparoscopy is commonly used by gynecologists, urologists, and general surgeons for abdominal and pelvic applications. Laparoscopy is also being used by orthopedic surgeons for spinal applications and by cardiac surgeons for minimally invasive heart surgery. Newer video-assisted laparoscopic procedures include **thyroidectomy** and **parathyroidectomy**.

Demographics

At first, laparoscopy was only performed on young, healthy adults, but the use of this technique has greatly expanded over time. Populations on whom laparoscopies are now performed include infants, children, the elderly, the obese, and those with chronic disease states, such as cancer. The applications of this type of surgery have grown considerably over the years to include a variety of patient populations, and will continue to do so with the refinement of laparoscopic techniques.

A U.S. study performed by researchers at the University of Massachusetts Medical Center from 1998 to 2006 using the Nationwide Inpatient Sample (NIS) found that 220,839 people underwent elective LAP surgery or open colectomy during that time. Of that number, 17,289 underwent **gastrectomy**; 9,174, **splenectomy**; 64,171, **nephrectomy**; and 5,556, **adrenalectomy**. Although increasing in popularity in the United States since its introduction in the early 1990s, LAP procedures still account for only a small percentage of total elective procedures: 3.8% of colectomy, 8.8% of splenectomy, 2.4% of gastrectomy, 7.0% of nephrectomy, and 14.2% of adrenalectomy. Most of these LAP procedures are performed in urban medical centers (94%) and in teaching centers (64%).

In another study performed at the Washington University School of Medicine (St. Louis), researchers found that distinct disparities exist in the access to laparoscopic surgery for **appendectomy** and **cholecystectomy** procedures. Using the University HealthSystem Consortium database from a period covering 2005 to 2009, 82,062 laparoscopic (72.9%) and 30,478 open (27.1%) procedures were performed. They found that people young in age, female in gender, white in race/ethnicity, and with minor illnesses and commercial or private insurance were more likely to have a laparoscopic procedure than an open procedure.

Description

Laparoscopy may be performed by a gynecologist, general surgeon, thoracic surgeon, gastroenterologist, or other physician, depending upon the patient's condition. An anesthesiologist or other specifically trained anesthesia personnel, such as a certified registered nurse anesthetist, is required during the procedure to administer general and/or local anesthesia and to perform patient monitoring. Nurses and surgical technicians/assistants are needed during the procedure to assist with scope positioning, camera operation, video system adjustments and image recording, and laparoscopic instrumentation.

WWW.BOOKBAZ.IR

Laparoscopy is typically performed in the hospital under general **anesthesia**, although some laparoscopic procedures can be performed using local anesthetic agents. Once under anesthesia, a urinary catheter is inserted into the patient's bladder for urine collection. To begin the procedure, a small incision is made just below the navel, and a cannula or trocar is inserted into the incision to accommodate the insertion of the laparoscope. Other incisions may be made in the abdomen to allow the insertion of additional laparoscopic instrumentation. A laparoscopic insufflation device is used to inflate the abdomen with carbon dioxide gas to create a space in which the laparoscopic surgeon can maneuver the instruments. After the laparoscopic diagnosis and treatment are completed, the laparoscope, cannula, and other instrumentation are removed, and the incision is sutured and bandaged.

Laparoscopes have integral cameras for transmitting images during the procedure, and these are available in various sizes depending upon the type of procedure performed. The images from the laparoscope are transmitted to a viewing monitor that the surgeon uses to visualize the internal anatomy and guide any surgical procedure. Video and photographic equipment are also used to document the surgery and may be used postoperatively to explain the results of the procedure to the patient.

Robotic systems are available to assist with laparoscopy. A robotic arm attached to the operating table may be used to hold and position the laparoscope. This serves to reduce unintentional camera movement that can occur when a surgical assistant holds the laparoscope. The surgeon controls the robotic arm movement by foot pedal with voice-activated command or with a handheld control panel.

Microlaparoscopy has become more common over the past few years. The procedure involves the use of smaller laparoscopes—2 millimeters (mm), compared to sizes from 5 mm to 10 mm for hospital laparoscopy—with the patient undergoing local anesthesia with conscious **sedation** in a physician's office. Video and photographic equipment may be used.

Laparoscopy has been explored in combination with other therapies for the treatment of certain types of malignancies, including pelvic and aortic lymph node dissection, **ovarian cancer**, and early **cervical cancer**. Laparoscopic radiofrequency ablation is a technique whereby laparoscopy assists in the delivery of radiofrequency probes that distribute pulses to a tumor site. The pulses generate heat in malignant tumor cells and destroys them.

The introduction of items such as temperature-controlled instruments, surgical instruments with greater rotation and articulation, improved imaging systems, and multiple robotic devices will expand the utility of laparoscopic techniques in the future. The skills of surgeons will be enhanced as well, with further development of training simulators and computer technology.

Preparation

Before undergoing laparoscopic surgery, the patient should be prepared by the doctor for the procedure both psychologically and physically. It is very important that the patient receives realistic counseling before surgery and prior to giving informed consent. This includes discussion about further open abdominal surgery (laparotomy) that may be required during laparoscopic surgery, information about potential complications during surgery, and the possible need for blood transfusions. In the case of diagnostic laparoscopy for chronic pelvic pain, the procedure may simply indicate that all organs are normal, and the patient should be prepared for this possibility. The surgery may be explained using pictures, models, videos, and movies. It is especially important for the patient to be able to ask questions and express concerns. It may be helpful for the patient to have a family member or friend present during discussions with the doctor to help take notes.

There is usually a presurgical examination two weeks before the surgery to gather a medical history and obtain blood and urine samples for laboratory testing. It is important that the patient inform the doctor completely about any prior surgeries, medical conditions, or medications taken on a regular basis, including **nonsteroidal anti-inflammatory drugs** (NSAIDs), such as **aspirin**; other over-the-counter medications; and **vitamins** and supplements. Patients taking blood thinners like warfarin (Coumadin) should never adjust their medication themselves and should speak with their prescribing doctors regarding their upcoming surgery. If a tubal dye study is planned during the procedure, the patient may also be required to provide information on menstrual history. For some procedures, an autologous **blood donation** may be suggested prior to the surgery to replace any blood lost during the procedure. Chest x-rays may also be required. For some obese patients, weight loss may be necessary prior to surgery.

Immediately before surgery, there are several preoperative steps that the patient may be advised to take. The patient should shower at least 24 hours prior

to the surgery and gently but thoroughly cleanse the umbilicus (belly button) with antibacterial soap and water using a cotton-tipped swab. Because laparoscopy requires general anesthesia in most cases, the patient may be asked to eat lightly 24 hours prior to surgery and fast at least 12 hours prior to surgery. Bowel cleansing with a laxative may also be required, which allows it to be more easily visualized and to prevent complications in the unlikely event of bowel injury. People with diabetes or **hypoglycemia** may wish to schedule their procedures early in the morning to avoid low blood sugar reactions. The patient should follow the directions of the hospital staff, arriving early on the day of surgery to sign paperwork and be screened by the anesthesiology staff. The patient will be asked questions regarding current medications and dosages, **allergies** to medication, previous experiences with anesthesia (that is, allergic reactions, and previous experiences regarding time-to-consciousness), and other topics. It is often helpful for the patient to make a list of this information beforehand so that it can be retrieved easily when requested by the hospital staff.

Aftercare

Following laparoscopy, patients are required to remain in a recovery area until the immediate effects of anesthesia subside and normal voiding is accomplished (especially if a urinary catheter was used during the surgery). Vital signs are monitored to ensure that there are no reactions to anesthesia or internal injuries present. There may be some nausea and/or **vomiting**, which may be reduced by the use of the anesthetic propofol for healthy patients undergoing elective procedures such as **tubal ligation**, diagnostic laparoscopy, or **hernia repair**. Laparoscopy is usually an outpatient procedure and patients are discharged from the recovery area within a few hours after the procedure. For elderly patients and patients with other medical conditions, recovery may be slower. Patients with more serious medical conditions or patients undergoing emergency laparoscopy may be required to stay overnight or longer.

Once patients are discharged, they will receive instructions regarding activity level, medications, postoperative dietary modifications, and possible side effects of the procedure. It may be helpful to have a friend or family member present when these instructions are given, as the aftereffects of anesthesia may cause some temporary confusion. Postoperative instructions may include information on when to resume normal activities such as bathing, housework, and driving. Depending on the nature of the laparoscopic procedure and the patient's medical condition, daily activity may be restricted for a few days and strenuous activity restricted for several days to weeks. Pain-relieving medications and **antibiotics** may be prescribed for several days postoperatively.

Patients will be instructed to watch for signs of a **urinary tract infection** (UTI) or unusual pain; either may indicate organ injury. It is important to understand the difference between normal discomfort and pain, because pain may indicate a problem. Patients may also experience an elevated temperature and occasionally a condition known as "postlaparoscopy syndrome"; this condition is similar in appearance to **peritonitis** (marked by abdominal pain, **constipation**, vomiting, and **fever**) that disappears shortly after surgery without antibiotics. Any postoperative symptoms that cause concern for the patient should be discussed with the doctor so that any fears can be alleviated. Due to the aftereffects of anesthesia, patients should not drive themselves home.

It is advisable for someone to stay with the patient for a few hours following the procedure, in case complications arise. Injury to an organ might not be readily apparent for several days after the procedure. The physical signs that should be watched for and reported immediately include:

- fever and chills
- abdominal distension
- vomiting
- difficulty urinating
- sharp and unusual pain in the abdomen or bowel
- redness at the incision site, which indicates infection
- discharge from any places where tubes were inserted or incisions were made

Additional complications may include a urinary tract infection (resulting from catheterization) and minor infection of the incision site. Abdominal distention or a pain in the flank may indicate an injury to the ureter. Additional testing may be required if a complication is suspected.

Results

In diagnostic laparoscopy, the surgeon will be able to see signs of a disease or condition (e.g., endometriosis adhesions, ovarian cysts, diseased gallbladder) immediately, and can either treat the condition surgically or proceed with appropriate medical management. In diagnostic laparoscopy, biopsies may be taken of tissue in questionable areas, and the laboratory results will determine the course of treatment. In therapeutic laparoscopy, the surgeon performs a procedure that rectifies a known medical problem, such as **hernia** repair or

WWW.BOOKBAZ.IR

appendix removal. Because laparoscopy is minimally invasive compared to open surgery, patients may experience less trauma and postoperative discomfort, have fewer procedural complications, have a shorter hospital stay, and return more quickly to daily activities. The results will vary, however, depending on the patients's condition and type of treatment.

Morbidity and mortality rates

Laparoscopic surgery, like most surgeries, is not without risk. Risks should be thoroughly explained to the patient. Complications from laparoscopic surgeries arise in 1% to 5% of the cases, with a mortality of about 0.05%. Complications may arise from the laparoscopic entry during procedure, and the risks vary depending on the elements specific to a particular procedure. For example, the risk of injury to the common bile duct in laparoscopic biliary surgery is 0.3% to 0.6% of cases. The factors that contribute to morbidity are currently under study and debate. Injury may occur to blood vessels and internal organs. Some studies examining malpractice data indicate that trocar injury to the bowel or blood vessels may account up to one-fourth of laparoscopic medical claims. It has been suggested that these injuries can be reduced by alterations in the placement and use of the Verses needle, or by using an open technique of trocar insertion in which a blunt cannula (non-bladed) is inserted into the abdominal cavity through an incision. The insertion of secondary trocars may be of particular interest as a risk factor. There is still some debate, however, as to which method of trocar insertion is most appropriate in a particular situation, as no technique is without risk. The most commonly cited injury in laparoscopic malpractice claims has been injury to the bile duct (66%). Proper identification of this structure by an experienced surgeon, or by a cholangiogram, may reduce this type of injury. Other areas of the body that may be injured during access include the stomach, bladder, and liver. Hemorrhages may also occur during the operation.

Risks

Complications may be associated with the laparoscopy procedure in general or may be specific to the type of operation that is performed. Patients should consult with their doctors regarding the types of risks that are specific for their procedures. The most serious complication that can occur during laparoscopy is laceration of a major abdominal blood vessel resulting from improper positioning, inadequate insufflation (inflation) of the abdomen, abnormal pelvic anatomy, and too much force exerted during scope insertion. Thin patients with well-developed abdominal muscles are at higher risk, since the aorta may only be an inch or so below the skin. Obese patients are also at higher risk because more forceful and deeper needle and scope penetration is required. During laparoscopy, there is also a risk of bleeding from blood vessels, and adhesions may require repair by open surgery if bleeding cannot be stopped using laparoscopic instrumentation. In laparoscopic procedures that use electrosurgical devices, **burns** to the incision site are possible due to passage of electrical current through the laparoscope caused by a fault or malfunction in the equipment.

Complications related to insufflation of the abdominal cavity include gas inadvertently entering a blood vessel and causing an **embolism**, pneumothorax, or subcutaneous **emphysema**. One common but not serious side effect of insufflation is pain in the shoulder and upper chest area for a day or two following the procedure.

Any abdominal surgery, including laparoscopy, carries the risk of unintentional organ injury (punctures and perforations). For example, the bowel, bladder, ureters, or fallopian tubes may be injured during the laparoscopic procedure. Many times these injuries are unavoidable due to the patient's anatomy or medical condition. Patients at higher risk for bowel injury include those with chronic bowel disease, PID, a history of pervious abdominal surgery, or severe endometriosis. Some types of laparoscopic procedures have a higher risk of organ injury. For instance, during laparoscopic removal of endometriosis adhesions or ovaries, the ureters may be injured due to their proximity to each other.

Several clinical studies have shown that the complication rate during laparoscopy is associated with inadequate surgeon experience. Surgeons who are more experienced in laparoscopic procedures have fewer complications than those performing their first 100 cases.

Alternatives

The alternatives to laparoscopy vary, depending on the medical condition being treated. Laparotomy (open abdominal surgery with larger incision) may be pursued when further visualization is needed to treat the condition, such as in the case of pain of severe endometriosis with deeper lesions. For female patients with pelvic masses, transvaginal sonography may be a helpful technique in obtaining information about whether such masses are malignant, assisting in the choice between laparoscopy or laparotomy.

KEY TERMS

Ascites—Accumulation of fluid in the abdominal cavity; laparoscopy may be used to determine its cause.

Autologous blood donation—Donation of the patient's own blood, made several weeks before elective surgery.

Cannula—A small, flexible tube.

Cholecystitis—Inflammation of the gallbladder, often diagnosed using laparoscopy.

Conscious sedation—A level of sedation during which the patient remains awake but very relaxed.

Electrosurgical device—A medical device that uses electrical current to cauterize or coagulate tissue during surgical procedures; often used in conjunction with laparoscopy.

Embolism—Blockage of an artery by a clot, air or gas, or foreign material. Gas embolism may occur as a result of insufflation of the abdominal cavity during laparoscopy.

Endometriosis—A disease involving occurrence of endometrial tissue (lining of the uterus) outside the uterus in the abdominal cavity; often diagnosed and treated using laparoscopy.

Hysterectomy—Surgical removal of the uterus; often performed laparoscopically.

Insufflation—Inflation of the abdominal cavity using carbon dioxide; performed prior to laparoscopy to give the surgeon space to maneuver surgical equipment.

Oophorectomy—Surgical removal of the ovaries; often performed laparoscopically.

Pneumothorax—Air or gas in the pleural space (lung area) that may occur as a complication of laparoscopy and insufflation.

Subcutaneous emphysema—A pathologic accumulation of air underneath the skin resulting from improper insufflation technique.

Trocar—A small sharp instrument used to puncture the abdomen at the beginning of the laparoscopic procedure.

Laryngeal cancer

Definition

Laryngeal cancer is cancer of the larynx or voice box.

Description

The larynx is located where the throat divides into the esophagus and the trachea. The esophagus is the tube that takes food to the stomach. The trachea, or windpipe, takes air to the lungs. The area where the larynx is located is sometimes called the Adam's apple.

The larynx has two main functions. It contains the vocal cords, cartilage, and small muscles that make up the voice box. When a person speaks, small muscles tighten the vocal cords, narrowing the distance between them. As air is exhaled past the tightened vocal cords, it creates sounds that are formed into speech by the mouth, lips, and tongue.

The second function of the larynx is to allow air to enter the trachea and to keep food, saliva, and foreign material from entering the lungs. A flap of tissue called the epiglottis covers the trachea each time a person swallows. This blocks foreign material from entering the lungs. When not swallowing, the epiglottis retracts, and air flows into the trachea. During treatment for cancer of the larynx, both of these functions may be lost.

Cancers of the larynx develop slowly. About 95% of these cancers develop from thin, flat cells similar to skin cells called squamous epithelial cells. These cells line the larynx. Gradually, the squamous epithelial cells begin to change and are replaced with abnormal cells. These abnormal cells are not cancerous but are pre-malignant cells that have the potential to develop into cancer. This condition is called dysplasia. Most people with dysplasia never develop cancer. The condition simply goes away without any treatment, especially if the person with dysplasia stops **smoking** or drinking alcohol.

The larynx is made up of three parts, the glottis, the supraglottis, and the subglottis. Cancer can start in any of these regions. Treatment and survival rates depend on which parts of the larynx are affected and whether the cancer has spread to neighboring areas of the neck or distant parts of the body.

The glottis is the middle part of the larynx. It contains the vocal cords. Cancers that develop on the vocal cords are often diagnosed very early because even small vocal cord tumors cause hoarseness. In addition, the vocal cords have no connection to the lymphatic system. This means that cancers on the vocal cord do not spread easily. When confined to the vocal cords without any involvement of other parts of the larynx, the cure rate for this cancer is 75–95%.

The supraglottis is the area above the vocal cords. It contains the epiglottis, which protects the trachea from foreign materials. Cancers that develop in this region are usually not found as early as cancers of the glottis because the symptoms are less distinct. The supraglottis region has many connections to the lymphatic system, so cancers in this region tend to spread easily to the lymph nodes and may spread to other parts of the body (lymph nodes are small bean-shaped structures that are found throughout the body; they produce and store infection-fighting cells). In 25–50% of people with cancer in the supraglottal region, the cancer has already spread to the lymph nodes by the time they are diagnosed. Because of this, survival rates are lower than for cancers that involve only the glottis.

The subglottis is the region below the vocal cords. Cancer starting in the subglottis region is rare. When it does, it is usually detected only after it has spread to the vocal cords, where it causes obvious symptoms such as hoarseness. Because the cancer has already begun to spread by the time it is detected, survival rates are generally lower than for cancers in other parts of the larynx.

About 12,000 new cases of cancer of the larynx develop in the United States each year. Each year, about 3,900 die of the disease. Laryngeal cancer is between four and five times more common in men

than in women. Almost all men who develop laryngeal cancer are over age 55. Laryngeal cancer is about 50% more common among African-American men than among other Americans.

It is thought that older men are more likely to develop laryngeal cancer than women because the two main risk factors for acquiring the disease are lifetime habits of smoking and alcohol abuse. More men are heavy smokers and drinkers than women, and more African-American men are heavy smokers than other men in the United States. However, as smoking becomes more prevalent among women, it seems likely that more cases of laryngeal cancer in females will be seen.

Causes and symptoms

Laryngeal cancer develops when the normal cells lining the larynx are replaced with abnormal cells (dysplasia) that become malignant and reproduce to form tumors. The development of dysplasia is strongly linked to life-long habits of smoking and heavy use of alcohol. The more a person smokes, the greater the risk of developing laryngeal cancer. It is unusual for someone who does not smoke or drink to develop cancer of the larynx. Occasionally, however, people who inhale asbestos particles, wood dust, paint or industrial chemical fumes over a long period of time develop the disease.

The symptoms of laryngeal cancer depend on the location of the tumor. Tumors on the vocal cords are rarely painful, but cause hoarseness. Anyone who is continually hoarse for more than two weeks or who has a **cough** that does not go away should be checked by a doctor.

Tumors in the supraglottal region above the vocal cords often cause more, but less distinct symptoms. These include:

- persistent sore throat
- pain when swallowing
- difficulty swallowing or frequent choking on food
- bad breath
- lumps in the neck
- persistent ear pain (called referred pain; the source of the pain is not the ear)
- change in voice quality

Tumors that begin below the vocal cords are rare, but may cause noisy or difficult breathing. All the symptoms above can also be caused other cancers as well as by less seriousness illnesses. However, if these symptoms persist, it is important to see a doctor and find their cause, because the earlier cancer treatment begins, the more successful it is.

Diagnosis

On the first visit to a doctor for symptoms that suggest laryngeal cancer, the doctor first takes a complete medical history, including family history of cancer and lifestyle information about smoking and alcohol use. The doctor also does a **physical examination**, paying special attention to the neck region for lumps, tenderness, or swelling.

The next step is examination by an otolaryngologist, or ear, nose, and throat (ENT) specialist. This doctor also performs a physical examination, but in addition will also want to look inside the throat at the larynx. Initially, the doctor may spray a local anesthetic on the back of the throat to prevent gagging, then use a long-handled mirror to look at the larynx and vocal cords. This examination is done in the doctor's office. It may cause gagging but is usually painless.

A more extensive examination involves a **laryngoscopy**. In a laryngoscopy, a lighted fiberoptic tube called a laryngoscope that contains a tiny camera is inserted through the patient's nose and mouth and snaked down the throat so that the doctor can see the larynx and surrounding area. This procedure can be done with a sedative and local anesthetic in a doctor's office. More often, the procedure is done in an outpatient surgery clinic or hospital under general **anesthesia**. This allows the doctor to use tiny clips on the end of the laryngoscope to take biopsies (tissue samples) of any abnormal-looking areas.

Laryngoscopies are normally painless and take about one hour. Some people find their throat feels scratchy after the procedure. Since laryngoscopies are done under **sedation**, patients should not drive immediately after the procedure, and should have someone available to take them home. Laryngoscopy is a standard procedure that is covered by insurance.

The locations of the samples taken during the laryngoscopy are recorded, and the samples are then sent to the laboratory where they are examined under the microscope by a pathologist who specializes in diagnosing diseases through cell samples and laboratory tests. It may take several days to get the results. Based on the findings of the pathologist, cancer can be diagnosed and staged.

Once cancer is diagnosed, other tests will probably be done to help determine the exact size and location of the tumors. This information is helpful in

WWW.BOOKBAZ.IR

determining which treatments are most appropriate. These tests may include:

- Endoscopy. Similar to a laryngoscopy, this test is done when it appears that cancer may have spread to other areas, such as the esophagus or trachea.
- Computed tomography (CT or CAT) scan. Using x-ray images taken from several angles and computer modeling, CT scans allow parts of the body to be seen as a cross section. This helps locate and size the tumors, and provides information on whether they can be surgically removed.
- Magnetic resonance imaging (MRI). MRI uses magnets and radio waves to create more detailed cross-sectional scans than computed tomography. This detailed information is needed if surgery on the larynx area is planned.
- Barium swallow. Barium is a substance that, unlike soft tissue, shows up on x rays. Swallowed barium coats the throat and allows x-ray pictures to be made of the tissues lining the throat.
- Chest x ray. Done to determine if cancer has spread to the lungs. Since most people with laryngeal cancer are smokers, the risk of also having lung cancer or emphysema is high.
- Fine needle aspiration (FNA) biopsy. If any lumps on the neck are found, a thin needle is inserted into the lump, and some cells are removed for analysis by the pathologist.
- Additional blood and urine tests. These tests do not diagnose cancer, but help to determine the patient's general health and provide information to determine which cancer treatments are most appropriate.

Treatment

Staging

Once cancer of the larynx is found, more tests will be done to find out if cancer cells have spread to other parts of the body. This is called staging. A doctor needs to know the stage of the disease to plan treatment. In cancer of the larynx, the definitions of the early stages depend on where the cancer started.

STAGE I. The cancer is only in the area where it started and has not spread to lymph nodes in the area or to other parts of the body. The exact definition of stage I depends on where the cancer started, as follows:

- Supraglottis: The cancer is only in one area of the supraglottis and the vocal cords can move normally.
- Glottis: The cancer is only in the vocal cords and the vocal cords can move normally.
- Subglottis: The cancer has not spread outside of the subglottis.

STAGE II. The cancer is only in the larynx and has not spread to lymph nodes in the area or to other parts of the body. The exact definition of stage II depends on where the cancer started, as follows:

- Supraglottis: The cancer is in more than one area of the supraglottis, but the vocal cords can move normally.
- Glottis: The cancer has spread to the supraglottis or the subglottis or both. The vocal cords may or may not be able to move normally.
- Subglottis: The cancer has spread to the vocal cords, which may or may not be able to move normally.

STAGE III. Either of the following may be true:

- The cancer has not spread outside of the larynx, but the vocal cords cannot move normally, or the cancer has spread to tissues next to the larynx.
- The cancer has spread to one lymph node on the same side of the neck as the cancer, and the lymph node measures no more than 3 centimeters (just over 1 inch).

STAGE IV. Any of the following may be true:

- The cancer has spread to tissues around the larynx, such as the pharynx or the tissues in the neck. The lymph nodes in the area may or may not contain cancer.
- The cancer has spread to more than one lymph node on the same side of the neck as the cancer, to lymph nodes on one or both sides of the neck, or to any lymph node that measures more than 6 centimeters (over 2 inches).
- The cancer has spread to other parts of the body.

RECURRENT. Recurrent disease means that the cancer has come back (recurred) after it has been treated. It may come back in the larynx or in another part of the body.

Treatment

Treatment is based on the stage of the cancer as well as its location and the health of the individual. Generally, there are three types of treatments for cancer of the larynx. These are surgery, radiation, and **chemotherapy**. They can be used alone or in combination based in the stage of the caner. Getting a second opinion after the cancer has been staged can be very helpful in sorting out treatment options and should always be considered.

SURGERY. The goal of surgery is to cut out the tissue that contains malignant cells. There are several common surgeries to treat laryngeal cancer.

Stage III and stage IV cancers are usually treated with total **laryngectomy**. This is an operation to remove the entire larynx. Sometimes other tissues around the larynx are also removed. Total laryngectomy removes the vocal cords. Alternate methods of voice communication must be learned with the help of a speech pathologist. Laryngectomy is treated in depth as a separate entry in this volume.

Smaller tumors are sometimes treated by partial laryngectomy. The goal is to remove the cancer but save as much of the larynx (and corresponding speech capability) as possible. Very small tumors or cancer in situ are sometimes successfully treated with laser excision surgery. In this type of surgery, a narrowly-targeted beam of light from a laser is used to remove the cancer.

Advanced cancer (Stages III and IV) that has spread to the lymph nodes often requires an operation called a neck dissection. The goal of a neck dissection is to remove the lymph nodes and prevent the cancer from spreading. There are several forms of neck dissection. A **radical neck dissection** is the operation that removes the most tissue.

Several other operations are sometimes performed because of laryngeal cancer. A **tracheotomy** is a surgical procedure in which an artificial opening is made in the trachea (windpipe) to allow air into the lungs. This operation is necessary if the larynx is totally removed. A **gastrectomy** tube is a feeding tube placed through skin and directly into the stomach. It is used to give **nutrition** to people who cannot swallow or whose esophagus is blocked by a tumor. People who have a total laryngectomy usually do not need a gastrectomy tube if their esophagus remains intact.

RADIATION. Radiation therapy uses high-energy rays, such as x rays or gamma rays, to kill cancer cells. The advantage of radiation therapy is that it preserves the larynx and the ability to speak. The disadvantage is that it may not kill all the cancer cells. Radiation therapy can be used alone in early stage cancers or in combination with surgery. Sometimes it is tried first with the plan that if it fails to cure the cancer, surgery still remains an option. Often, radiation therapy is used after surgery for advanced cancers to kill any cells the surgeon might not have removed.

There are two types of radiation therapy. External beam radiation therapy focuses rays from outside the body on the cancerous tissue. This is the most common type of radiation therapy used to treat laryngeal cancer. With internal radiation therapy, also called brachytherapy, radioactive materials are placed directly on the cancerous tissue. This type of radiation therapy is a much less common treatment for laryngeal cancer.

External radiation therapy is given in doses called fractions. A common treatment involves giving fractions five days a week for seven weeks. Clinical trials are underway to determine the benefits of accelerating the delivery of fractions (accelerated fractionation) or dividing fractions into smaller doses given more than once a day (hyperfractionation). Side effects of radiation therapy include **dry mouth**, **sore throat**, hoarseness, skin problems, trouble swallowing, and diminished ability to taste.

CHEMOTHERAPY. Chemotherapy is the use of drugs to kill cancer cells. Unlike radiation therapy, which is targeted to a specific tissue, chemotherapy drugs are either taken by mouth or intravenously (through a vein) and circulate throughout the whole body. They are used mainly to treat advanced laryngeal cancer that is inoperable or that has metastasized to a distant site. Chemotherapy is often used after surgery or in combination with radiation therapy. Clinical trials are underway to determine the best combination of treatments for advanced cancer.

The two most common chemotherapy drugs used to treat laryngeal cancer are cisplatin and 5-fluorouracil (5-FU). There are many side effects associated with chemotherapy drugs, including **nausea and vomiting**, loss of appetite, hair loss, **diarrhea**, and mouth sores. Chemotherapy can also damage the blood-producing cells of the bone marrow, which can result in low blood cell counts, increased chance of infection, and abnormal bleeding or bruising.

Alternatives

Alternative and complementary therapies range from herbal remedies, vitamin supplements, and special **diets** to spiritual practices, **acupuncture**, massage, and similar treatments. When these therapies are used in addition to conventional medicine, they are called complementary therapies. When they are used instead of conventional medicine, they are called alternative therapies.

Complementary or alternative therapies are widely used by people with cancer. One large study published

WWW.BOOKBAZ.IR

in the *Journal of Clinical Oncology* in July 2000 found that 83% of all cancer patients studied used some form of complementary or alternative medicine as part of their cancer treatment. No specific alternative therapies have been directed toward laryngeal cancer. However, good nutrition and activities that reduce **stress** and promote a positive view of life have no unwanted side-effects and appear to be beneficial in boosting the immune system in fighting cancer.

Unlike traditional pharmaceuticals, complementary and alternative therapies are not evaluated by the United States Food and Drug Administration (FDA) for either safety or effectiveness. These therapies may have interactions with traditional pharmaceuticals. Patients should be wary of "miracle cures" and notify their doctors if they are using herbal remedies, vitamin supplements or other unprescribed treatments. Alternative and experimental treatments normally are not covered by insurance.

Prognosis

Cure rates and survival rates can predict group outcomes, but can never precisely predict the outcome for a single individual. However, the earlier laryngeal cancer is discovered and treated, the more likely it will be cured.

Cancers found in stage 0 and stage 1 have a 75% to 95% cure rate depending on the site. Late stage cancers that have metastasized have a very poor survival rate, with intermediate stages falling somewhere in between. People who have had laryngeal cancer are at greatest risk for recurrence (having cancer come back), especially in the head and neck, during the first two to three years after treatment. Check-ups during the first year are needed every other month, and four times a year during the second year. It is rare for laryngeal cancer to recur after five years of being cancer-free.

Prevention

By far, the most effective way to prevent laryngeal cancer is not to smoke. Smokers who quit smoking also significantly decrease their risk of developing the disease. Other ways to prevent laryngeal cancer include limiting the use of alcohol, eating a well-balanced diet, seeking treatment for prolonged **heartburn**, and avoiding inhaling asbestos and chemical fumes.

KEY TERMS

Dysplasia—The abnormal change in size, shape or organization of adult cells.

Lymph—Clear, slightly yellow fluid carried by a network of thin tubes to every part of the body. Cells that fight infection are carried in the lymph.

Lymphatic system—Primary defense against infection in the body. The lymphatic system consists of tissues, organs, and channels (similar to veins) that produce, store, and transport lymph and white blood cells to fight infection.

Lymph nodes—Small, bean-shaped collections of tissue found in a lymph vessel. They produce cells and proteins that fight infection, and also filter lymph. Nodes are sometimes called lymph glands.

Metastasize—Spread of cells from the original site of the cancer to other parts of the body where secondary tumors are formed.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Laryngectomy

Definition

A laryngectomy is the partial or complete surgical removal of the voice box (larynx).

Purpose

Because of its location, the voice box, or larynx, plays a critical role in breathing, swallowing, and speaking. The larynx is located above the windpipe (trachea) and in front of the food pipe (esophagus). It contains two small bands of muscle called the vocal cords that close to prevent food from entering the lungs and vibrate to produce the voice. If cancer of the larynx develops, a laryngectomy is performed to remove tumors or cancerous tissue. In rare cases, the procedure may also be performed when the larynx is badly damaged by gunshot, automobile injuries, or other traumatic accidents.

Demographics

According to the National Cancer Institute, 12,260 new cases of **laryngeal cancer** were diagnosed in the United States in 2013. Tobacco **smoking** is by far the greatest risk factor for laryngeal cancer. Others include alcohol abuse, radiation exposure, asbestos exposure, and genetic factors.

Description

A laryngectomy is usually performed by an otolaryngologist in a hospital operating room. In the case of **trauma** to the throat, the procedure may be performed by an emergency room physician.

Laryngectomies may be total or partial. In a total laryngectomy, the entire larynx is removed. If the cancer has spread to other surrounding structures in the neck, such as the lymph nodes, they are removed at the same time. If the tumor is small, a partial laryngectomy is performed, in which only a part of the larynx, usually one vocal chord, is removed. Partial laryngectomies are also often performed in conjunction with other cancer treatments, such as **radiation therapy** or **chemotherapy**.

During a laryngectomy, the surgeon removes the larynx through an incision in the neck. The procedure also requires the surgeon to perform a **tracheotomy**, because air can no longer flow into the lungs. He or she makes an artificial opening called a stoma in the front of the neck. The upper portion of the trachea is brought to the stoma and secured, making a permanent alternate way for air to get to the lungs. The connection between the throat and the esophagus is not normally affected, so after healing, the person whose larynx has been removed can eat normally.

Preparation

A laryngectomy is performed after cancer of the larynx has been diagnosed by a series of tests that allow the otolaryngologist (a physician often called an ear, nose and throat, or ENT specialist) to examine the throat and take tissue samples (biopsies) to confirm and stage the cancer. People need to be in good general health to undergo a laryngectomy, and will have standard preoperative blood work and tests to make sure they are able to safely withstand the operation.

As with any surgical procedure, the patient is required to sign a consent form after the procedure is thoroughly explained. Blood and urine studies, along with **chest x-ray** and EKG may be ordered as required. If a total laryngectomy is planned, the patient meets with a speech pathologist for discussion of postoperative expectations and support.

Aftercare

A person undergoing a laryngectomy spends several days in intensive care (ICU) and receives intravenous (IV) fluids and medication. As with any major surgery, blood pressure, pulse, and respiration are monitored regularly. The patient is encouraged to turn, **cough**, and deep-breathe to help mobilize secretions in the lungs. One or more drains are usually inserted in the neck to remove any fluids that collect. These drains are removed after several days.

KEY TERMS

Larynx—Also known as the voice box, the larynx is composed of cartilage that contains the apparatus for voice production. This includes the vocal cords and the muscles and ligaments that move the cords.

Lymph nodes—Accumulations of tissue along a lymph channel, which produce cells called lymphocytes that fight infection.

Tracheotomy—A surgical procedure in which an artificial opening is made in the trachea (windpipe) to allow air into the lungs.

It takes two to three weeks for the tissues of the throat to heal. During this time, the patient cannot swallow food and must receive **nutrition** through a tube inserted through the nose and down the throat into the stomach. Normal speech is also no longer possible and patients are instructed in alternate means of vocal communication by a speech pathologist.

When air is drawn in normally through the nose, it is warmed and moistened before it reaches the lungs. When air is drawn in through the stoma, it does not have the opportunity to be warmed and humidified. In order to keep the stoma from drying out and becoming crusty, patients are encouraged to breathe artificially humidified air. The stoma is usually covered with a light cloth to keep it clean and to keep unwanted particles from accidentally entering the lungs. Care of the stoma is extremely important, since it is the person's only way to get air to the lungs. After a laryngectomy, a healthcare professional will teach the patient and his or her caregivers how to care for the stoma.

There are three main methods of vocalizing after a total laryngectomy. In esophageal speech, patients learn how to "swallow" air down into the esophagus and create sounds by releasing the air. Tracheoesophageal speech diverts air through a hole in the trachea made by the surgeon. The air then passes through an implanted artificial voice. The third method involves using a hand-held electronic device that translates vibrations into sounds. The choice of vocalization method depends on several factors including the age and health of the patient, and whether other parts of the mouth, such as the tongue, have also been removed (glossectomy).

Results

Ideally, removal of the larynx will remove all cancerous material. The person will recover from the operation, make lifestyle adjustments, and return to an active life.

Morbidity and mortality rates

The American Cancer Society estimated that 3,630 people died of laryngeal cancer in 2013; of these, 2,860 were men and 770 were women.

Risks

Laryngectomy is often successful in curing early stage cancers; however, it requires major lifestyle changes and there is a risk of severe psychological **stress** from unsuccessful adaptations. Patients must learn new ways of speaking and they must be constantly concerned about the care of their stoma. Serious problems can occur if water or other foreign material enters the lungs through an unprotected stoma. Also, women who undergo partial laryngectomy or who learn some types of artificial speech will have a deep voice similar to that of a man. For some women this presents psychological challenges. As with any major operation, there is a risk of infection. Infection is of particular concern to patients who have chosen to have a voice prosthesis implanted and is one of the major reasons for having to remove the device.

Alternatives

Radiation and chemotherapy are two alternatives forms of treatment. Radiation therapy uses high-energy rays (such as x-rays) to kill or shrink cancer cells. Chemotherapy uses drugs to kill cancer cells. The drugs are usually delivered into a vein or by mouth. Once the drugs enter the bloodstream, they spread throughout the body to the cancer site.

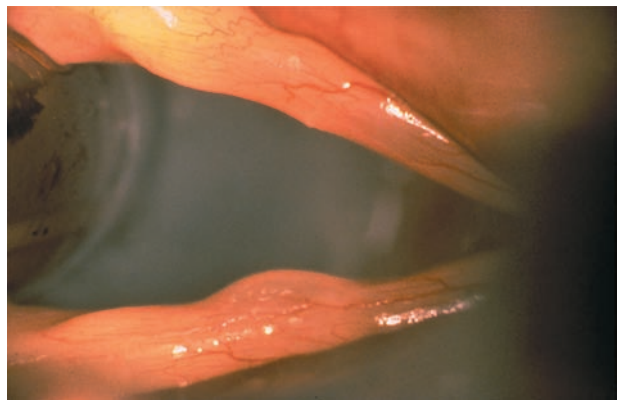
Laryngitis

Definition

Laryngitis, one type of dysphonia (disorders of the voice), is caused by inflammation of the larynx, resulting in distortion (hoarseness) of the voice. Sometimes irritation of the vocal cords, which are contained within the larynx, causes a complete, but temporary, loss of the voice. Acute laryngitis usually lasts for less than a few days and usually causes only strain on the vocal cords, while the chronic form of the inflammation can extend out to several weeks and may cause serious problems.



An endoscopic view of a patient's vocal cords with laryngitis. *(Custom Medical Stock Photo, Inc.)*

Demographics

The disorder is found in both children and adults, and is equally common in all races of people all over the world. It is equally prevalent in men and women.

Description

When air is breathed in (inspired), it passes through the nose and the nasopharynx or through the mouth and the oropharynx. These are both connected to the larynx, a tube made of cartilage. The vocal cords, responsible for setting up the vibrations necessary for speech, are located within the larynx. They consist of two folds of mucous membrane, which surround muscle and cartilage. The air continues down the larynx to the trachea. The trachea then splits into two branches, the left and right bronchi (bronchial tubes). These bronchi branch into smaller air tubes which run within the lungs, leading to the small air sacs of the lungs (alveoli).

Either food, liquid, or air may be taken in through the mouth. While air goes into the larynx and the respiratory system, food and liquid are directed into the tube leading to the stomach, the esophagus. Because food or liquid in the bronchial tubes or lungs could cause a blockage or lead to an infection, the airway must be protected. The epiglottis is a leaf-like piece of cartilage extending upwards from the larynx. The epiglottis can close down over the larynx when someone is eating or drinking, preventing these substances from entering the airway.

WWW.BOOKBAZ.IR

In laryngitis, the tissues below the level of the epiglottis are swollen and inflamed. This causes swelling around the area of the vocal cords, so that they cannot vibrate normally. A hoarse sound to the voice is very characteristic of laryngitis. Laryngitis is a very common problem, and often occurs during the course of an upper respiratory tract infection (cold).

Causes and symptoms

Acute laryngitis is caused almost 100% of the time by a virus. The same viruses that cause the majority of simple upper respiratory infections (colds, **bronchitis**, etc.), along with the **mumps** and **measles**, are responsible for laryngitis. These include human parainfluenza viruses (HPIVs), influenzavirus A, human respiratory syncytial virus (RSV), human rhinovirus, coronaviruses, and enteric cytopathic human orphan virus (ECHO virus). Extremely rarely, bacteria such as Group A streptococcus bacterium (*Streptococcus pyogenes*), *Moraxella catarrhalis*, or those strains of mycobacteria (usually *Mycobacterium tuberculosis*) that cause **tuberculosis** may cause laryngitis. In people with faulty immune systems (particular due to acquired **immunodeficiency** syndrome, or **AIDS**), infections with fungi may be responsible for laryngitis. In addition, factors that can contribute to laryngitis include **allergies**, acid reflux disease or similar problems, alcohol consumption, **smoking** tobacco products, and excessive coughing.

Chronic laryngitis is usually caused by strain to the vocal cords from inhaled irritants (chemical fumes, smoke, etc.), excessive alcohol use, chronic **sinusitis**, smoking, acid reflux, and excessive use of the voice (singers, etc.). It can also be caused, although less frequently, by bacterial, fungal, or parasitic infections. Chronic laryngitis can also be caused by cancer or tumors, **vocal cord paralysis** (from injuries, strokes or other health problems, and age-related problems).

Symptoms usually begin along with, or following, symptoms of a cold. A sore, scratchy, dry throat; **fever**; runny nose; achiness; and **fatigue** may all occur. Difficulty swallowing sometimes occurs with **streptococcal infections**. The patient may **cough** and wheeze. Most characteristically, the patient's voice will sound weak, strained, hoarse, and raspy. Sometimes the voice is temporarily lost. Swollen lymph nodes in the throat, face, or chest may also be present.

In extremely rare cases, the swelling of the larynx may cause symptoms of airway obstruction. This is more common in infants, because the diameter of their airways is so small. In that case, the baby may have a greatly increased respiratory rate, and exhibit loud high-pitched sounds with breathing (called **stridor**). In other cases, blood may be coughed up, increased production of saliva in the mouth may be present, and difficulties in eating may also occur.

Diagnosis

A visit to the doctor is necessary if such symptoms last for over a few days. If hoarseness remains for more than two weeks, then a trip to a physician is wise. For children, always seek medical care if the child has trouble swallowing, difficulty breathing, a body temperature of over 103°F (39°C), excessive drooling, and noisy, high-pitched sounds while inhaling. When at the health-care professional, diagnosis is usually made by learning the history of a cold followed by hoarseness. The throat usually appears red and somewhat swollen. Listening to the chest and back with a stethoscope may reveal some harsh **wheezing** sounds with inspiration (breathing in).

In long-standing (chronic laryngitis), tuberculosis may be suspected. Using a scope called a laryngoscope, examination of the airway will show redness, swelling, small bumps of tissue called nodules, and irritated pits in the tissue called ulcerations. The medical professional will examine the back of the throat with a small, lighted mirror. In some cases, a fiberoptic **laryngoscopy** may be performed. In such procedures, an endoscope with a small camera and light is inserted into the nose or mouth so that the physician can examine the throat and, especially, watch the action of the vocal cords while the patient is speaking.

In other cases, the medical team may analyze a sample of tissue suspected as part of the laryngitis. The biopsy will be removed and taken to a medical laboratory where it will be examined under a microscope. In still other cases, special skin testing (TB testing) will reveal whether the individual has been exposed to the bacteria causing tuberculosis (TB).

Treatment

Treatment of a simple, viral laryngitis simply addresses the symptoms. Gargling with warm salt water, **pain** relievers such as **acetaminophen**, the use of vaporizers to create moist air, and rest will help the illness resolve within a week. **Corticosteroids** may sometimes be used to reduce inflammation. However, such medication is usually only used in certain cases, such as when the laryngitis is more severe or there is an urgent need to recover more quickly.

KEY TERMS

Epiglottis—A leaf-like piece of cartilage extending upwards from the larynx, which can close like a lid over the trachea to prevent the airway from receiving any food or liquid being swallowed.

Larynx—The part of the airway lying between the pharynx and the trachea.

Nasopharynx—The part of the airway into which the nose leads.

Oropharynx—The part of the airway into which the mouth leads.

Trachea—The part of the airway which leads into the bronchial tubes.

Antibiotic or anti-fungal medication may be prescribed or given if the laryngitis is due to a bacterial or fungal infection, respectively.

In an infant who is clearly struggling for air, it may be necessary to put in an artificial airway for a short period of time. This is very rarely needed.

An individual with tubercular laryngitis is treated with a combination of medications used to treat classic TB. In people with fungal laryngitis, a variety of anti-fungal medications are available.

If laryngitis is caused by gastroesophageal reflux, sometimes also called **gastroesophageal reflux disease** (GERD), the person may be given ranitidine hydrochloride (Zantac) or omeprazole (Prilosec) for one to two months.

For laryngitis patients with severe hoarseness a visit to the voice pathologist or laryngologist may be necessary. In some cases **speech therapy** or a various surgical procedures may be recommended. People who sing or others who use their voices frequently (such as teachers) may be asked to rest their voice until it returns to normal.

Alternatives

Alternative treatments include **aromatherapy** inhalations made with benzoin, lavender, frankincense, thyme, and sandalwood. Decoctions (extracts made by boiling an herb in water) or infusions (extracts made by steeping an herb in boiling water) can be made with red sage (*Salvia officinalis* var. *rubra*) and yarrow (*Achillea millefolium*) or with licorice (*Glycyrrhiza glabra*). These are used for gargling, and are said to reduce pain. **Echinacea** (*Echinacea* spp.) tincture taken in water every hour for 48 hours is recommended to boost the immune system. Antiviral herbs, including usnea (*Usnea* spp.), lomatium (*Lomatium dissectum*), and ligusticum (*Ligusticum porteri*), may help hasten recovery from laryngitis. Homeopathic remedies are recommended based on the patient's symptoms. Some people may get relief from placing cold compresses on the throat.

Prognosis

Prognosis for laryngitis is excellent. Recovery is complete, and usually occurs within a week's time.

Prevention

Prevention of laryngitis is the same as for any upper respiratory infections. The only way to even attempt to prevent such illnesses is by good hand washing, and by avoiding situations where one might come in contact with people who might be sick. However, even with relatively good hygiene practices, most people will get about five to six colds per year. It is unpredictable which of these may lead to laryngitis.

In addition, do not smoke and avoid situations where second-hand smoke may be present. Also, drink plenty of water daily to keep the throat moist.

Laryngoscopy

Definition

Laryngoscopy refers to a procedure used to view the inside of the larynx (the voice box).

Description

The purpose and advantage of seeing inside the larynx is to detect tumors, foreign bodies, nerve or structural injury, or other abnormalities. Two methods allow the larynx to be seen directly during the examination. In one, a flexible tube with a fiber-optic device is threaded through the nasal passage and down into the throat. The other method uses a rigid viewing tube passed directly from the mouth, through the throat, into the larynx. A light and lens affixed to the endoscope are used in both methods. The endoscopic tube may also be equipped to suction debris or remove material for biopsy. **Bronchoscopy** is a similar, but more extensive procedure in which the tube is continued through the larynx, down into the trachea and bronchi.

Preparation

Laryngoscopy is done in the hospital with a local anesthetic spray to minimize discomfort and suppress the gag reflex. Patients are requested not to eat for several hours before the examination.

Aftercare

If the throat is sore, soothing liquids or lozenges will probably relieve any temporary discomfort.

Results

A normal result would be the absence of signs of disease or damage.

An abnormal finding, such as a tumor or an object lodged in the tissue, would either be removed or described for further medical attention.

Risks

This procedure carries no serious risks, although the patient may experience soreness of the throat or **cough** up small amounts of blood until the irritation subsides.

Laser-assisted in situ keratomileusis (LASIK)

Definition

Laser-assisted in situ keratomileusis (LASIK) is a non-reversible refractive procedure performed by ophthalmologists to correct **myopia**, **hyperopia**, or **astigmatism**. The surgeon uses an excimer laser to cut or reshape the cornea so that light will focus properly on the retina.

Purpose

LASIK is an elective surgery for patients who want to permanently correct myopia (nearsightedness), hyperopia (farsightedness), or astigmatism without eyeglasses, **contact lenses**, or refractive surgical procedures. The goal for most patients is to be free of any type of corrective lenses. Some patients may find wearing eyeglasses or contact lenses interferes with their careers or hobbies. Many professional athletes have chosen LASIK to improve their performance; however, patients with higher degrees of refractive error will still need some type of corrective lens.

LASIK is most commonly performed on myopes. For myopia, the surgeon flattens the cornea; for hyperopia, the surgeon steepens the cornea. Surgeons correct astigmatism by creating a normally shaped cornea with the excimer laser.

A new type of LASIK also can treat contrast sensitivity as well as refractive error. Custom LASIK incorporates new eye mapping technology into standard LASIK. The surgeon measures the eye from front to back creating a three dimensional corneal map. This much-more detailed map gives surgeons more specific information for the excimer laser and enables them to correct other abnormalities besides refractive error.

Demographics

LASIK candidates have myopia, hyperopia, or astigmatism; are 18 or older; and have had stable vision for at least two years. More than 17.5 million

LASIK procedures have been performed in the United States since its introduction.

The first LASIK patients in the late 1990s were in the upper class, or upper middle class, and in their early 30s to mid-40s. The market was limited for the elective procedure that at first could range as expensive as $5,000 per eye. The number of younger patients receiving LASIK (in their early to mid-20s) was expected to rise in 2003 and beyond. The number of procedures also was expected to increase as prices continued to stabilize, and surgery centers and physicians offered payment plans.

Description

An ophthalmologist performs LASIK, but because it is a relatively new technology, the surgeon may not have received training as part of his or her residency. It is more likely the surgeon has completed continuing medical education courses or may have had training provided by the laser companies. He or she may also have received training as part of membership in an organization such as the American Society of Refractive Surgeons.

Before and aftercare probably will be provided by a co-managing optometrist. The optometrist usually performs the pre- and postoperative exams, and also discusses the patient's suitability for LASIK and any potential problems.

Ophthalmic technicians may perform preliminary testing, including corneal topography and corneal measuring. Laser technicians are required to have special training provided by the laser manufacturer.

Surgeons may perform LASIK in a hospital where they rely on the hospital staff for support. Because lasers are expensive, some surgeons pool their resources and purchase a laser that they share at a freestanding surgery center. LASIK is also provided by surgeons at surgery centers owned by refractive surgery companies. These businesses hire support staff, optometrists, and surgeons to perform LASIK.

Origins

LASIK is a relatively new procedure. In April 1985, German physician Theo Seiler was the first to use an excimer laser to attempt to correct astigmatism in blind eyes. Experiments with excimer lasers on blind eyes were also completed in the United States in the mid-1980s. The term LASIK was invented by Greek ophthalmologist Ioannis Pallikari, the first surgeon to use the hinged flap technique. Dr. Stephen Brint, as part of a clinical trial in 1991, performed the first LASIK procedure in the United States.

There are two main types of LASIK: the standard LASIK procedure and custom LASIK.

Standard LASIK

Standard LASIK takes from 10 to 20 minutes to perform and the results are immediate. It's standard practice in LASIK operating rooms to have a clock on the wall so patients immediately can note they are able to read a clock face or other items that previously were blurry.

Immediately before the procedure, the ophthalmologist may request corneal topography (a corneal map) to compare with previous maps to ensure the treatment plan is still correct. The surgeon may also measure the cornea's thickness if it was not done previously. After these tests, a technician or co-managing optometrist will perform a refraction to make sure the refractive correction the surgeon will program into the laser is correct.

Three sets of eye drops will be administered twice before surgery. The first drop anesthetizes the cornea, the second drop prevents infection and the third drop controls inflammation after LASIK. Patients may be given a sedative, such as Valium. This is administered to calm nervous patients or to help patients sleep after the procedure.

After the prep work is completed, the patient reclines on a laser bed and the surgeon is seated directly behind the patient. If the procedure is being done on both eyes on the same day, the surgeon will patch the second eye. An eyelid speculum is inserted in the eye to be treated first to hold the eyelids apart. The patient stares at the blinking light of a laser microscope and must fixate his or her gaze on that light. The patient must remain still throughout the procedure.

The surgeon checks the refractive numbers on the laser. Because each patient's cornea is shaped differently, the surgeon may have to adjust the level of correction. Laser companies provide an algorithm to determine the correction level, and the surgeon may alter the level because of a patient's special needs. The adjustments are called nomograms. After the adjustments, the surgeon checks the microkeratome blade for defects.

The surgeon then indents the cornea to mark the flap location. The surgeon places a suction ring in the center of the sclera. A technician will activate the microkeratome's suction. The patient's vision dims at this point. The surgeon tests pressure by touching the cornea with a tonometer. Before using the microkeratome, sterile saline solution is squirted into the suction ring to lubricate the cornea. The microkeratome

head is placed in the gear tracks of the suction ring, and the surgeon guides the microkeratome across the suction ring to create a flap. The microkeratome stops just short of traveling completely across the cornea. It leaves a hinge of tissue, commonly called a flap. After the flap is created, the surgeon removes the suction ring and slips a spatula under it and moves it to the side, exposing the stroma (inner cornea).

Once the stroma is exposed, the laser ablation begins, ranging from 30 to 60 seconds. The ablation flattens the cornea of myopic patients; steepens the cornea of hyperopic patients; and reshapes the cornea of astigmatic patients. After the ablation, the surgeon replaces the flap. More saline solution is squirted to remove any debris and enable the flap to move back into place without interruption. The surgeon ensures the flap is in place and removes any wrinkles. The surgeon places a shield over the eye to keep the flap in place. No stitches are used.

If bilateral LASIK is being performed, the patient must remain still while being prepared for treatment on the remaining eye.

Custom LASIK

About half of all LASIK procedures are deemed "custom" LASIK. The difference between standard LASIK and custom LASIK lies in the diagnosis and who can be treated. With custom LASIK, surgeons use a wavefront analyzer (aberrometer) that beams light through the eye and finds irregularities based on how the light travels through the eye. It creates a three-dimensional corneal map to create a customized pattern for each patient. For standard LASIK, each patient with the same refractive error is treated with the same setting on the excimer laser, barring a few adjustments. The new technology individualizes treatment not only for refractive errors, but also for visual disorders that previous corneal mapping technology could not detect. Other types of custom LASIK include bladeless LASIK.

Besides the customized excimer laser, the surgical procedure is the same. Surgeons now can treat patients who have higher-order aberrations, such as contrast sensitivity—therefore, custom LASIK can successfully treat glare, night vision and other contrast problems.

Preparation

Before LASIK, patients need to have a complete eye evaluation and comprehensive medical history taken. Soft contact lens wearers should stop wearing their lenses at least one week before the initial exam. Gas permeable lens wearers should not wear their lenses from three weeks to a month before the exam. Contact lens wear can alter the cornea's shape, which should be allowed to return to its natural shape before the initial exam.

The initial exam

During the first exam, the surgeon's staff will take a comprehensive medical history to determine if there are underlying medical problems that will prevent a successful surgery. This screening process will determine patients who should not have the procedure including:

- pregnant women or women who are breast-feeding
- patients with very small or very large refractive errors
- patients with low contrast sensitivity
- patients with scarred corneas or macular disease
- people with autoimmune diseases
- diabetics
- glaucoma patients
- patients with persistent blepharitis

The physician will also ask about medication. Some prescription medicines have been known to cause postsurgical scarring or cause flecks under the corneal flap. It is important for the patient to disclose any prescriptions or over-the-counter medicines taken regularly. **Allergies** to prescription medicine must also be discussed.

A complete eye exam will be performed to determine refractive error, uncorrected visual acuity, and best corrected visual acuity. A cycloplegic refraction using eye drops to dilate the pupils also will be performed. Other examination procedures include corneal mapping, a keratometer reading to determine the curvature of the central part of the cornea, and a slit lamp exam to determine any damage to the cornea and evidence of **glaucoma** and **cataracts**. A fundus exam also will be performed to check for retinal holes and **macular degeneration** and macular disease. Other tests are done to rule out glaucoma.

While those tests check general eye health, others more closely relate to the outcome of LASIK surgery. A corneal pachymeter measures the cornea's thickness. This is important because surgeons remove tissue during surgery. A pupilometer measures the pupil when it is naturally dilated in a dark room without drops. Patients with large pupils have been known to have complications after LASIK, such as glare and halos.

Treatment options

After the exam, the patient and physician discuss treatment options and expectations. Patients who expect to see perfectly after LASIK are usually not considered good candidates because they usually are dissatisfied with the results. Surgeons also discuss how patients will handle **presbyopia**, which occurs during the patient's 40s. LASIK does not correct for presbyopia, and patients will need reading glasses to accommodate for reading when presbyopia occurs. Sometimes patients 40 and older opt for monovision to treat presbyopia, where one eye is left untreated or one eye is only partially corrected. Monovision means one eye is for short-term vision and the other is for distance vision.

The doctor will advise the patient of any possible LASIK complications, explain the procedure and answer questions. After deciding on a treatment option, the patient is required to sign an informed consent form.

At this time, payment will also be discussed. Insurance usually does not cover LASIK, although some offer a limited benefit for the procedure. Some laser centers offer payment plans and some physicians have begun using credit companies to handle payments. LASIK can cost anywhere from $999 to $3,000 per eye. The cost varies greatly from surgeon to surgeon. Most of the fees are global, and cover all the preoperative and postoperative exams as well as the procedure. Patients should be advised of what the fee covers, and if retreatments to the original surgery are included in that price.

Presurgery preparations

The patient is advised to discontinue contact lens wear immediately and refrain from using creams, lotions, make-up or perfume for at least two days before surgery. Patients may also be asked to scrub their eyelashes for a period of time to remove any debris. Patients also must find transportation to and from the surgery, and also to and from the first postoperative visit. Medication and distorted vision make it unsafe for the patients to drive after LASIK.

Aftercare

After LASIK, patients may experience burning, **itching** or a foreign body sensation. They should be advised not to touch the eye as that could damage the flap. Many physicians recommend sleeping after the surgery. Patients may also experience glare, starbursts, or halos that should improve after the first few days. Patients are advised to seek help immediately if they feel severe eye **pain**, or if symptoms worsen.

The first follow-up visit is 24–48 hours after surgery. The physician will remove the eye shield, check the patient's vision, and may prescribe more antibiotic drops or artificial tears. Patients must refrain from strenuous activity, such as contact sports, for at least a month. The use of creams, lotions, and make-up must also be avoided for at least two weeks. Hot tubs and swimming pools should be avoided for at least two months. Patients are advised that refraining from these activities and products will help stem infection and aid healing of the cornea.

Patients will have regularly scheduled visits post-LASIK for at least six months. Vision gradually improves the first few months after surgery. In some cases, if the vision does not meet expectations and the surgeon believes it can be further corrected, he or she will perform an enhancement. Enhancements are usually done for undercorrection. Overcorrected patients usually need eyeglasses or contact lenses.

Results

After LASIK, most patients are able to see well enough to pass a driver's license exam without glasses or contact lenses. Some patients will still need corrective lenses, but the lenses won't need to be as powerful.

Because LASIK is a relatively new procedure, there is limited information on long-term regression. If patients are being treated for myopia, they should be aware they will have to rely on spectacles with the onset of presbyopia.

Morbidity and mortality rates

Information about mortality rates following LASIK is limited because the procedure is elective. Complications that can lead to more serious conditions, such as infection, are treated with **topical antibiotics** after LASIK. The most serious possible complication from LASIK is blindness from an untreated complication. One incidence of legal blindness was reported after a severely myopic patient had retinal hemorrhages; however, it was inconclusive whether or not LASIK was the causative agent.

According to the American Academy of Ophthalmology, up to 10.5% of patients who undergo LASIK in the United States require a second treatment.

Risks

Surgeons separate LASIK complications into two categories: intraoperative risks during surgery and postoperative complications.

WWW.BOOKBAZ.IR

Intraoperative risks include:

- Cornea perforation. This complication has almost disappeared because of advances in microkeratome design.
- Flap complications. Newer microkeratomes also have reduced the likelihood of "free caps," where the cap becomes unhinged. An experienced surgeon replaces the cap after ablation. In some cases, the procedure must be aborted while the eye heals.
- Laser hot spots. Higher energy surrounding the laser beam can cause irregular astigmatism. Proper laser testing before the procedure eliminates this risk.
- Central islands. This refers to a raised area in the central part of the treated zone that receives insufficient laser treatment. Any raised area can decrease the laser's effectiveness. The island either shrinks by itself or can be remedied with retreatment.
- Decentered ablation. This occurs when the laser beam is aimed incorrectly. This can result in permanent halos and ghost images.

Postoperative complications include:

- Undercorrection or overcorrection. Undercorrection can usually be treated with an enhancement, but overcorrection will require the use of eyeglasses or contact lenses.
- Debilitating symptoms. These can be permanent or transient, and include glare, halos, double vision and poor nighttime vision. Some patients may also lose contrast sensitivity.
- Dry eye. This also can be permanent or transient. Most patients experience some dry eye immediately after surgery. Some patients continue to experience dry eye and are treated with artificial tears or punctal plugs.
- Displaced flap. Occurs after the eye is hit or rubbed. If immediate attention is given by the surgeon, who must lift the flap and clean under it, no long-term effects occur.
- Nonspecific diffuse intralamellar keratitis. Commonly known as Sands of the Sahara, this complication can range from corneal haze to eye clouding that resembles swirling sand. It is treated with topical steroids, although severe cases may require eye irrigation.
- Epithelial ingrowth. The cells of the lower cornea migrate under the corneal cap. The surgeon must lift the cap and remove the cells. If untreated, vision is impaired.
- Striae. These are wrinkles in the flap that can reduce visual acuity. The surgeon must lift the corneal flap and smooth the wrinkles.
- Photophobia. Extreme sensitivity to light can last a few days or a week after surgery.
- Infection. This rarely occurs after LASIK. It is treated with antibiotics.

Alternatives

Nonsurgical alternatives

Nonsurgical alternatives to LASIK are contact lenses and eyeglasses, which can also correct refractive errors. Continuous-wear contact lenses, which a patient can sleep in for as long as 30 days, can provide the same effect as LASIK if the patient wants good vision upon waking. Orthokeratology involves a rigid gas permeable contact lens the patient wears for a predetermined amount of time to reshape the cornea. After removing the lens, it takes weeks for the cornea to return to its normal shape. At that time, the patient repeats the process.

Corneal rings and implants are another alternative for myopes. These require surgery without lasers and involve a corrective lens surgically implanted in the eye. One of the biggest benefits to these procedures is that they are reversible; however, they may not provide the crisp vision of a successful LASIK. There also are several different types of intraocular lenses being tested to treat myopia and hyperopia.

Surgical alternatives

There also are surgical alternatives to LASIK. They include:

- Conductive keratoplasty. This uses radio frequency waves to shrink corneal collagen. It is used to treat mild to moderate hyperopia.
- Photorefractive keratectomy (PRK). PRK also uses an excimer laser and is similar to LASIK; however, in PRK, the surface of the cornea is removed by the laser. PRK patients have a longer recovery time and may need steroidal eye drops for months after surgery. Its success rate is similar to that of LASIK.
- Radial keratotomy (RK). RK was the first widely used surgical correction for mild to moderate myopia. The surgeon alters the shape of the cornea without a laser. This is one of the oldest refractive procedures, and has proved successful on lower and moderate corrections.

- Astigmatic keratotomy (AK). AK is a variation of RK used to treat mild to moderate astigmatism. AK has proved successful if the errors are mild to moderate.
- Laser thermal keratoplasty (LTK). LTK was approved as to treat hyperopia in 2000. An LTK patient's vision is overcorrected for one to three months, and the effect of improved near vision may diminish over time as distance vision improves. Some regression has been noted.
- Laser epithelial keratomileusis (LASEK). This variation on LASIK removes the epithelium using a fine blade and an alcohol solution. Once the cornea is reshaped, the epithelial flap is replaced.

Laser skin resurfacing

Definition

Laser **skin resurfacing** involves the application of laser light to the skin in order to remove fine wrinkles and tighten the skin surface. It is most often used on the skin of the face.

Purpose

The purpose of laser skin resurfacing is to use the heat generated by extremely focused light to remove the upper to middle layers of the skin. This procedure eliminates superficial signs of **aging** and softens the appearance of other lesions such as **scars**. Upon healing, the surface of the skin has a younger appearance. Microscopic analysis of skin after laser resurfacing shows that the healed surface more closely resembles younger, healthier skin in many aspects.

Demographics

According to the American Society of Plastic Surgeons, there were more than 509,055 laser skin resurfacing procedures performed in the United States in 2012. Almost all persons of sufficient age have one or more symptoms of aging or damaged skin that can be treated by this procedure, including fine lines in the skin, known as rhytides; discoloration of the skin; **acne** scarring; and surgical or other types of scars.

Description

The procedure is performed by an experienced laser surgeon or a dermatological surgeon with special training in the use of the laser. It is performed in a special suite adapted for laser use, often located at the surgeon's offices.

A central component of the laser skin resurfacing technique is the laser device. Laser is an acronym for light amplification by stimulated emission of radiation. This device produces an intense beam of light of a specific, known wavelength. Laser light is produced by high-energy stimulation of different substances such as crystals, liquid dyes, and gases. For skin resurfacing, two types of lasers produce light that is well absorbed by the upper to middle layers of the skin: light produced from carbon dioxide gas (CO_2) and light produced from a crystal made of erbium, yttrium, aluminum, and garnet (Er:YAG). Combination lasers are also commercially available.

There are as yet no standard parameters for laser use in all skin resurfacing procedures. Settings are

WWW.BOOKBAZ.IR

KEY TERMS

Acetic acid—Vinegar; very dilute washes of the treated areas with a vinegar solution are suggested by some surgeons after laser skin resurfacing.

Carbon dioxide—Abbreviated CO_2; a gas that produces light that is well absorbed by the skin, so is commonly used for skin resurfacing treatments.

Erbium:YAG—A crystal made of erbium, yttrium, aluminum, and garnet that produces light that is well absorbed by the skin, so it is used for skin resurfacing treatments.

Hydrogel—A gel that contains water, used as a dressing after laser skin resurfacing.

Milia—Small bumps on the skin that occur when sweat glands are clogged.

Rhytides—Very fine wrinkles, often of the face.

Topical—Applied to the skin surface.

determined on a case-by-case basis by the laser surgeon who relies on his or her own experience.

Before the procedure begins, medication is often given to relax the patient and reduce **pain**. For small areas, local topical (surface-applied) anesthetics are often used to numb the area to be treated. Alternatively, for large areas, nerve block-type **anesthesia** is used. Some laser surgeons use conscious **sedation** (twilight anesthesia) alone or in combination with other techniques.

During the procedure, the patient lies on his or her back on the surgical table, eyes covered to protect them from the laser light. Laser passes are performed over the area being treated, utilizing computer control of the laser for precise results. In general, more passes are needed with Er:YAG lasers than carbon dioxide laser treatment.

Because areas of the body other than the face have relatively low numbers of the cells central to the healing process, laser skin resurfacing is not generally used anywhere but on the face; used elsewhere, the healing process may be slow and can result in scarring.

Preparation

An initial consideration is to determine which laser would be best for any particular skin resurfacing procedure. Carbon dioxide lasers have been in use longer and have been shown to produce very good results; however, the healing times tend to be long and redness can persist for several months. In contrast, because the light produced by the Er:YAG laser is more efficiently absorbed by the skin, less light energy and shorter pass times can be used, which significantly shortens the healing time. Unfortunately, the results obtained with this laser have not been as consistently good as with a carbon dioxide laser. Patients should therefore discuss the two laser types and the condition of their skin with their doctor to determine which would be better for their particular situation.

Although controversial, some studies have reported abnormal scarring in patients previously treated with 13 cis-retinoic acid (Accutane), so many surgeons will require a six-month break from the medication before performing laser skin resurfacing.

Laser skin resurfacing does increase the chance of recurrent or initial herpes simplex virus infection (**cold sores**) during the healing process. Even with no patient history of the problem, it is important that anti-viral medicine is administered before, the morning of, and following laser skin resurfacing.

Aftercare

After the procedure, any treated areas are dressed for healing. Surgeons are divided on whether the wound should remain open or closed (covered) during the healing process. For example, surgeons that adopt a closed procedure can use a dressing that is primarily hydrogel held on a mesh support to cover the wound. This kind of dressing is changed daily while the epithelium (outer layer of skin) is restored. Open wound care involves frequent soaks in salt water or dilute acetic acid, followed by application of ointment. Whatever wound treatment is used, it is important to keep the healing skin hydrated.

Full restoration of the epithelial layer occurs in seven to ten days after treatment with a carbon dioxide laser and three to five days after treatment with an Er:YAG laser, although redness can persist for many weeks afterward.

Results

Normal results of this procedure include reduction in the fine lines found in aging skin, improving skin texture, making skin coloration more consistent, and softening the appearance of scars. In a recent study, more than 93% of patients subjectively rated their results from the procedure either very good or excellent.

Morbidity and mortality rates

The morbidity and mortality rates for this cosmetic procedure are close to zero.

Risks

Risks of this procedure include skin redness that persists beyond the initial healing period, swelling, burning sensations, or **itching**. These risks tend to be short term and lessen over time. More long-term problems can include scarring, increased or decreased pigmentation of the skin, and infection during healing. Finally, the formation of milia—bumps that form due to obstruction of the sweat glands—can occur, although this can be treated after healing with retinoic acid.

Alternatives

Surgical techniques such as face lifts or **blepharoplasty** (eyelid surgery) are often recommended when facial aging is beyond the restorative powers of a laser treatment and the most common alternative technique. Patients should also consider other skin resurfacing techniques such as dermabrasion or chemical peels, as these are more effective than laser resurfacing for certain skin conditions and certain skin types.

Laser surgery

Definition

The term "laser" means light amplification by stimulated emission of radiation. Laser surgery uses a laser light source to remove or treat tissues that are diseased or unwanted, to seal blood vessels that are bleeding, or to terminate tumors or lesions. Laser beams are strong beams of light produced by electrically stimulating a particular material—most often carbon dioxide, argon, or neodymium for surgery. The special light beam is focused to treat tissues by heating the cells until they burst.

Purpose

Sometimes described as "scalpels of light," lasers are used alone or with conventional surgical instruments in an array of procedures that improve appearance, relieve **pain**, restore function, and save lives. Routine uses of lasers include eliminating **birthmarks**, skin discoloration, and skin changes due to **aging**, as well as removing benign, precancerous, or cancerous tissues or tumors. Lasers may be used to remove tonsils, remove or transplant hair, remove tattoos, or relieve pain and restore function in patients who are too weak to undergo major surgery. They can seal lymph vessels to minimize swelling and decrease the spread of tumor cells. Lasers are also used to treat:

- angina (chest pain)
- cancerous or noncancerous tumors that cannot be removed or destroyed
- cold and canker sores, gum disease, and tooth sensitivity or decay
- ectopic pregnancy (development of a fertilized egg outside the uterus)
- endometriosis

- nosebleeds
- ovarian cysts
- painful nerve endings
- snoring

Description

Although many laser surgeries can be performed in a doctor's office rather than in a hospital, the person guiding the laser must be at least as thoroughly trained and highly skilled as someone performing the same procedure in a hospital setting. The American Society for Laser Medicine and Surgery urges that:

- all operative areas be equipped with oxygen and other drugs and equipment required for cardiopulmonary resuscitation (CPR)
- nonphysicians performing laser procedures be properly trained, licensed, and insured
- a qualified and experienced supervising physician be able to respond to and manage unanticipated events or other emergencies within five minutes of the time they occur
- emergency transportation to a hospital or other acute care facility (ACF) be available whenever laser surgery is performed in a nonhospital setting

Lasers are used to perform many surgical procedures. Lasers of various wavelengths are used to remove, cut, and vaporize tissue. Oftentimes, lasers can take the place of conventional surgical tools—scalpels, cryosurgery probes, electrosurgical units, or

microwave devices—to carry out standard procedures such as **mastectomy** (breast surgery). By using lasers, surgeons can accomplish more complex tasks without increasing the risk to the patient. The heat generated by the laser keeps the surgical site free of germs and reduces the risk of infection. Because a smaller incision is required, laser procedures often take less time, reducing the risk of complications from **anesthesia**, and cost less money than traditional surgery. Sealing off blood vessels and nerves reduces bleeding, swelling, scarring, pain, and the length of the recovery period. Also, because lasers are so precise, the laser can penetrate to the correct tissue depth simply by adjusting the intensity of the light.

History

The first working laser was introduced in 1960. The device was first used to treat diseases and disorders of the eye, whose transparent tissues gave ophthalmic surgeons a clear view of how the narrow, concentrated beam was being directed. Dermatologic surgeons also helped to pioneer laser surgery and developed and improved upon many early techniques and more refined surgical procedures.

Types of lasers

There are three types of lasers most often used in medical treatment:

- Carbon dioxide (CO_2) lasers are primarily surgical lasers. They convert light energy to heat strong enough to minimize bleeding while cutting through or vaporizing tissue.
- Neodymium:yttrium-aluminum-garnet (Nd:YAG) lasers are capable of penetrating tissue more deeply than other lasers. The Nd:YAG laser enables blood to clot quickly, allowing surgeons to see and touch body parts that could otherwise be reached only through open (invasive) surgery.
- Argon lasers provide the limited penetration needed for eye surgery and superficial skin disorders. In a special procedure known as photodynamic therapy (PDT), this laser uses light-sensitive dyes to shrink or dissolve tumors.

Laser applications

Lasers are extremely useful in both open and laparoscopic procedures. Some of the most common procedures include breast surgery, **hernia repair**, **bowel resection**, hemorrhoidectomy, gallbladder removal, and solid organ surgery. Laser surgery is often a standard operating procedure for specialists in:

- cardiology (disorders and diseases of the heart)
- dentistry (disorders and diseases of the teeth)
- dermatology (disorders and diseases of the skin)
- gastroenterology (disorders and diseases of the stomach and intestines)
- gynecology (disorders and diseases of women)
- neurosurgery (disorder and diseases of the nervous system)
- oncology (cancers)
- ophthalmology (disorders and diseases of the eye)
- orthopedics (disorders and diseases of bones, joints, muscles, ligaments, and tendons)
- otolaryngology (disorders and diseases of the ears, nose, and throat)
- pulmonology (disorders and diseases of the respiratory system)
- urology (disorders and diseases of the urinary tract and of the male reproductive system)

Precautions

Some types of laser surgery should not be performed on pregnant women or on patients with severe cardiopulmonary disease or other serious health problems. Additionally, if the procedure is being performed under general anesthesia, those risks should be fully discussed with the anesthesiologist. The patient should fully disclose all over-the-counter, herbal, and prescription medications that are being taken, as some can interact with agents used in anesthesia. All potential risks, precautions, and complications should be discussed by the doctor with the patient.

Because some lasers can temporarily or permanently discolor the skin, dark-skinned patients should make sure that the surgeon has successfully performed laser procedures on other patients with similar skin tones. Potential problems include infection, pain, scarring, and changes in skin color.

Preparation

Because laser surgery is used to treat so many diverse conditions, patients should ask their physician for detailed instructions about how to prepare for a specific procedure. Diet, activities, and medications may not have to be limited prior to surgery, but some procedures require a **physical examination** and medical history. This enables the doctor to evaluate the patient's general health and medical status; provides the doctor with information about how the patient has responded to other illnesses, hospital stays, and procedures; and clarifies what the patient expects in regard to the outcome of the procedure.

WWW.BOOKBAZ.IR

Aftercare

Most laser surgeries can be performed on an outpatient basis, and patients usually are permitted to leave the hospital or medical office when their vital signs have stabilized. A patient who has been sedated should not be discharged until recovery from the anesthesia is complete, unless a responsible adult is available to accompany the patient home.

The doctor may prescribe analgesic (pain-relieving) medication and should provide easy-to-understand, written instructions on how to take the medication. The doctor should also be able to give the patient a good estimate of how recovery will progress, the recovery time, and what to do in case complications or an emergency arises. The amount of time it takes for the patient to recover from surgery depends on the surgery and on the individual. Recovery time for laser surgery is, for the most part, shorter than for traditional surgery.

Results

A patient who is considering any kind of laser surgery should ask the doctor to provide detailed information about what the outcome of the surgery is expected to be, what the recovery process will involve, and how long it will be before normal appearance is regained and the patient can resume normal activities. Depending on the procedure, successful surgeries can enable patients to feel better, look younger, and enjoy longer, fuller, more active lives.

People considering laser surgery should also ask their doctor about potential abnormal outcomes. Lighter or darker skin may appear, for example, when a laser is used to remove sun damage or age spots from an olive-skinned or dark-skinned individual. This abnormal pigmentation may or may not disappear over time.

Scarring or rupturing of the cornea is uncommon, but laser surgery on one or both eyes can:

- increase sensitivity to light or glare
- reduce night vision
- permanently cloud vision, or cause sharpness of vision to decline throughout the day

Signs of infection following laser surgery include:

- burning
- crusting of the skin
- itching
- pain
- scarring
- severe redness
- swelling

KEY TERMS

Argon—A colorless, odorless gas.

Astigmatism—A condition in which one or both eyes cannot filter light properly and images appear blurred and indistinct.

Carbon dioxide—A heavy, colorless gas that dissolves in water.

Cauterize—To use heat or chemicals to stop bleeding, prevent the spread of infection, or destroy tissue.

Cornea—The outer, transparent lens that covers the pupil of the eye and admits light.

Endometriosis—An often painful gynecologic condition in which endometrial tissue migrates from the inside of the uterus to other organs inside and beyond the abdominal cavity.

Glaucoma—A disease of the eye in which increased pressure within the eyeball can cause gradual loss of vision.

Invasive surgery—A form of surgery that involves making an incision in the patient's body and inserting instruments or other medical devices into it.

Laparoscopic procedures—Surgical procedures during which surgeons rely on a laparoscope—a pencil-thin instrument that has its own lighting system and miniature video camera. To perform surgeries, only small incisions are needed to insert the instruments and the miniature camera.

Nearsightedness—A condition in which one or both eyes cannot focus normally, causing objects at a distance to appear blurred and indistinct. Also called myopia.

Ovarian cyst—A benign or malignant growth on an ovary. An ovarian cyst can disappear without treatment or become extremely painful and have to be surgically removed.

Vaporize—To dissolve solid material or convert it into smoke or gas.

Varicose veins—Swollen, twisted veins, usually occurring in the legs, which occur more often in women than in men.

Risks

Like traditional surgery, laser surgery can be complicated by hemorrhages, infection, or perforation (piercing) of an organ or tissue. Laser surgery can also involve risks that are not associated with

traditional surgical procedures. Laser beams can burn or destroy healthy tissue, cause injuries that are painful and sometimes permanent, or even compound problems they are supposed to solve. Errors or inaccuracies in laser surgery can worsen a patient's vision, for example, and lasers can scar and change the skin color of some patients. In certain procedures, if the physician is neglectful, the laser can severely burn the patient's lungs. In addition, patients must wear protective eye shields while undergoing laser surgery on any part of the face near the eyes or eyelids, and the U.S. Food and Drug Administration has said that doctors, staff, and patients must use special wavelength-specific, protective eyewear whenever a CO_2 laser is used.

There are also other dangers associated with laser surgery. Laser beams have the capacity to ignite clothing, paper, and hair. Furthermore, the risk of fire from lasers increases in the presence of oxygen. Hair should be protected and clothing should be tied back, or removed, within the treatment areas. It is also important to guard against electric shock, as lasers require the use of high voltage. Proper wiring is essential in any installation involving laser technology.

Late effects of childhood cancer and its treatment

Definition

Late effects of childhood cancer treatment may be defined as any adverse effect of treatment that does not resolve after treatment is completed or which appears after the completion of the treatment for cancer. Late effects can include adverse effects on major organ systems, problems with cognitive and psychosocial functioning as well as the development of second malignancies.

Demographics

Due to the effectiveness of treatment modalities in treating childhood cancers, deaths from these cancers have decreased dramatically over the last 50 years. Before 1970, virtually all children diagnosed with cancer died from the disease. Today, with current therapy, 79% of children affected by cancer are able to be cured. The numbers of survivors of childhood cancers are increasing with an estimated one long-term childhood cancer survivor among every 450 adolescents and young adults in the United States. There are approximately 300,000 long-term childhood cancer survivors

WWW.BOOKBAZ.IR

in the United States alone. Two-thirds of childhood cancer survivors will develop at least one late adverse effect as a result of their treatment for cancer.

Description

As ever-increasing numbers of children are surviving cancer, follow-up of these survivors has focused attention on adverse effects which may occur sometimes years after receiving treatment for childhood cancer. Many of these adverse effects become evident as the child matures into **puberty** and young adulthood. Many young cancer survivors have at least one organ system which has been impacted either by the cancer or by treatment for the cancer.

Late effects can be caused by **chemotherapy**, **radiation therapy**, hematopoietic stem cell transplant, and/or surgery. Virtually any organ of the body can be affected. According to the Children's Oncology Group of the American Academy of Pediatrics, the risk of late effects is directly related to the intensity of the cancer therapy received as treatment. Treatment methodologies which increase risk for late effects include longer treatment with higher doses of chemotherapy and radiation therapy, therapy which includes more than one treatment modality, e.g., a combination of chemotherapy and radiation as opposed to using only one of the modalities alone, and receiving therapy to treat relapse of disease. The patient's age at the time of the treatment also influences the potential for adverse late effects with younger children being at higher risk. Young children are particularly susceptible to the effects of cancer treatments which can result in impaired growth, cognitive function, sexual development, and organ function.

Most of the time, chemotherapy results in immediate and acute effects. However, some late effects of treatment with chemotherapy can develop. For example, treatment with chemotherapy drugs classified as alkylating agents can lead to problems such as delayed or arrested puberty and **infertility** and can result in the development of a different or second cancer. Treatment with radiation therapy can impede normal growth and development, can impair organ function and can lead to the development of cancer as well.

Late effects by organ system

Neurocognitive effects

Tests of cognitive function and academic achievement in childhood cancer survivors confirm the negative impact of radiation therapy targeted to the brain in infants and children. The negative effects are especially pronounced in survivors of the brain cancer, medulloblastoma, because of the higher doses of radiation therapy experienced by those survivors.

Neurocognitive effects such as seizures, **memory loss**, and decrease in cognitive function as evidenced by lower IQ and mathematics scores are associated with cranial radiation therapy and intrathecal administration of chemotherapy used in the treatment of children with acute lymphoblastic leukemia (ALL). Studies of children with brain tumors who were treated with surgery and radiation to the brain reveal similar neurocognitive deficits. Children who were younger than 3 years of age when treated experience more pronounced negative neurocognitive consequences.

Cardiac effects

Damage to the heart and cardiovascular system can occur as a result of treatment with radiation therapy that includes all or part of the heart in the treatment field. Childhood survivors of Hodgkin disease or those who received radiation to the spine as treatment for some brain tumors are at increased risk. Late effects of radiation therapy which included the heart in the treatment field includes pericardial effusions, constrictive **pericarditis** and premature **coronary artery disease**.

Childhood cancer survivors, especially infants and toddlers, who were treated with chemotherapy drugs classified as anthracyclines are at higher risk for the development of heart damage including anthracycline-induced **cardiomyopathy**. The use of anthracycline chemotherapy in children can also lead to the development of **congestive heart failure**, pericarditis, and ventricular **arrhythmias**. **Mitral valve insufficiency** can also occur as a late effect.

Pulmonary effects

Cancer treatments which can affect the lungs and result in late effects include radiation therapy and chemotherapy. Late effects of radiation therapy develop over a period of months and even years resulting in pneumonitis and **pulmonary fibrosis**.

Chemotherapy agents which can cause long-term adverse effects to the lungs include bleomycin, which is used in the treatment of children with **germ cell tumors** and lymphoma, and nitrosureas such as carmustine, which are used in the treatment of children with brain tumors. Pulmonary damage is increased when these agents are used in combination with radiation therapy. Adverse effects include pneumonitis and other pulmonary toxicities.

Endocrine and reproductive effects

Radiation therapy and treatment with chemotherapy agents classified as alkylating agents can lead to endocrine toxicity. Endocrine toxicity can negatively affect growth which can result in short stature.

Chemotherapy agents, particularly nitrogen mustard, procarbazine, and cyclophosphamide are the most damaging to the reproductive system. Young women treated with these drugs in combination with radiation may undergo **premature menopause** with the average age at **menopause** in one study at age 31 years. Young women who experience early menopause are then at increased risk of **osteoporosis** and **heart disease** at an earlier age than the general population.

Radiation to the reproductive organs in childhood can lead to fertility problems in men and in women in later years. Results of a study released in 2010 revealed that women who received radiation to the pelvic region prior to menarche were 12 times more likely to experience **stillbirth** and neonatal death of their offspring. In women treated with radiation therapy after menarche there was no significantly increased risk irregardless of the dose of radiation. In males, radiation to the testes did not affect risk for stillbirth or neonatal death rates of offspring nor was risk increased for the offspring of men and women who were treated in childhood with alkylating chemotherapy agents.

Children, particularly girls, diagnosed with acute lymphoblastic leukemia (ALL) and who were treated with higher doses of cranial irradiation, are more likely to develop **obesity** as a late effect.

Damage to the thyroid gland can also occur after radiation to the neck and/or chest.

Risk for second malignancies

Childhood cancer survivors who were treated with radiation therapy, chemotherapy or both modalities combined are at increased risk for the development of second malignant neoplasm (cancer). Risk for the development of a second cancer is related to the total dose received of chemotherapy and/or radiation therapy. Higher doses are correlated with increased risk of malignancy development.

Chemotherapy agents classified as alkylating agents especially nitrogen mustard, cyclophosphamide, ifosfamide, melphalan, and procarbazine damage DNA which can result in the development of a second malignancy such as acute myelogenous leukemia (AML). AML typically occurs 4–8 years after treatment for the first malignancy with alkylating agents.

Treatment with chemotherapy drugs classified as epipodophyllotoxins, such as etoposide and teniposide, can also result in the development of leukemia. In one study, about 12% of patients treated with acute lymphoblastic leukemia (ALL) developed secondary AML which is almost always fatal.

The risk of developing a second cancer after treatment with radiation therapy is related to the age of the patient at the time of the treatment and the total dose received. The risk of developing the second malignancy increases with time with as many as 20 years elapsing before the development of the secondary cancer. The most common second malignant neoplasms to develop include **breast cancer** after radiation to the chest as part of treatment for Hodgkin disease, brain tumors after radiation to the brain and central nervous system for the treatment of ALL, soft tissue **sarcomas**, and bone, thyroid and bladder cancers.

KEY TERMS

Cardiomyopathy—A disease or disorder which affects the heart muscle.

Intrathecal—Administration of chemotherapy drugs injected into the cerebrospinal fluids which surround the brain and spinal cord.

Pericardial effusion—An accumulation of excess fluid in the pericardial sac which surrounds the heart.

Pneumonitis—Inflammation of the lungs.

Pulmonary fibrosis—Scarring of lung tissue.

Prevention

Prevention of late effects of cancer therapies is receiving increased scrutiny and is generating substantial amounts of research as increased numbers of children survive cancer. Current treatment protocols attempt to treat childhood cancer while sparing normal tissues and organs as much as possible. Newer therapies and radiation techniques allow for more precise targeting of therapies. In addition, radiation therapy and some chemotherapy agents may be omitted or delayed in very young children. Other drugs, known as chemoprotectants, can be utilized to lessen the known toxicities of some chemotherapy drugs.

Latex allergy

Definition

A latex allergy is a reaction to latex, the natural rubber material that is found in certain medical and dental supplies and many other items people use, such as some baby pacifiers, balloons, **condoms**, or shoe soles.

Demographics

Between 1% and 5% of people have a latex allergy. The **allergies** are more common in people who are exposed to latex more often, usually people who work in health care, emergency medical care, or in the rubber industry. About 50% of people who have latex allergies have another type of allergy as well. Latex allergies also are more common in people who have **spina bifida** and certain abnormalities from birth that affect the urogenital area, or the organs that are involved in reproduction and excreting waste. Children are at slightly higher risk of developing latex allergies than adults, because many adults have been exposed to latex over the years. Men and women have equal incidence of latex allergies.

Description

Latex is a natural rubber product that comes from the milky fluid in the rubber tree. Latex stretches and is flexible, so it is chosen as the material to make many products used in medical offices, clinics, and hospitals. Examples of home and medical products made of latex are:

- household rubber gloves
- medical gloves
- pacifiers
- baby bottle nipples
- rubber bands
- condoms
- diaphragms
- adhesive tape and bandages
- diapers
- rubber toys
- tires
- elastic in clothing, such as waistbands

Risk factors

The latex rubber contains certain proteins that cause an allergic reaction in some people. Those most at risk are people who have allergies to foods with similar proteins, such as avocadoes and bananas. Anyone with allergies such as hay **fever** has a slightly higher risk, as well. Although a person can react to latex without touching it, people who work in occupations that require frequent contact with latex products are at highest risk for latex allergies. Nurses, doctors, medical technicians, emergency responders, dentists, and dental workers are a few examples. Other workers at high risk are housekeepers, food preparers, and cosmetologists. People with diseases that expose them to latex often as patients for medical procedures are at higher risk for latex allergies than others.

Causes and symptoms

Latex allergies are caused by exposure to the proteins in latex. Aside from the factors that put some people at higher risk, there are no other causes. People become sensitized to the allergen, which triggers their immune system to respond when near latex. The amount of latex it takes to cause an allergic reaction varies depending on the person. Some people can have an allergic reaction just by breathing latex particles in the air, while others only react if they touch latex products. Usually softer, stretchy latex products like surgical gloves are more likely to cause allergies than harder rubber products such as tires.

Symptoms

The symptoms of latex allergy vary depending on the person and whether the allergy is mild or severe. Most people who have been exposed to latex before and who have developed an allergic sensitivity have the following symptoms:

- coughing or wheezing
- itchy, red, and watery eyes
- itchy throat
- hives or a rash
- sneezing or a runny nose

These symptoms are uncomfortable but not serious; however, some people who are allergic to latex develop a severe and rapid anaphylactic reaction that can be life threatening. Symptoms of **anaphylaxis** typically involve more than one part of the body and can include:

- difficulty breathing
- confusion
- dizziness
- hives, welts, or a rash
- nausea
- vomiting, diarrhea, or stomach cramping
- problems swallowing
- pale or red skin

A person who has an anaphylactic reaction because of exposure to latex needs immediate medical attention.

Some people may react to latex due to a condition known as **contact dermatitis**, which causes **rashes** and even pimple-like bumps on the skin when their skin comes in contact with irritants. The latex is one of many materials that causes the person's skin to be irritated, mostly because of chemicals added to the rubber in manufacturing instead of the proteins in the sap. Contact **dermatitis** produces red, scaly, itchy skin where the irritant touched the skin.

Diagnosis

Sometimes, the cause of the symptoms from latex allergies is unknown—especially if symptoms do not occur until a few days after exposure to latex particles, or if the patient did not know that he or she had a latex allergy or that an item contained latex. For example, a child might blow up and play with balloons at a birthday party, or a family might have new carpeting installed that has latex rubber backing, but symptoms might appear a day or two after these events. The patient's medical history, such as other known allergies and recent activities, are important to diagnosing latex allergy.

Examination

The doctor will examine the patient to look for signs of an allergic reaction, such as rashes, **hives**, and swollen mucous membranes, or signs of more serious anaphylactic **shock** in an emergency setting. When the patient is having an anaphylactic reaction, there is no time to run laboratory tests, and the first priority is to reverse the symptoms. During an examination from mild effects or a follow-up after a serious reaction, the doctor looks for signs of diseases or conditions that cause similar symptoms to compare them and help determine whether the cause is latex allergy or some other problem. People with latex allergies often are referred by their primary physicians to see allergists or immunologists, doctors who specialize in these types of diseases.

Tests

In a nonemergency, the doctor might order blood tests to determine if the patient has certain elevated substances that indicate an allergy, especially to latex proteins. The tests are particularly helpful in confirming that a person has a latex allergy when latex is suspected as the cause of symptoms. Skin testing is not used often for latex allergy but can be performed when necessary by an allergist or immunologist.

Treatment

The most effective treatment for latex allergies is avoidance of latex exposure. Health care workers should be made aware of a patient's latex allergy so they can use equipment that does not contain latex whenever possible. When avoiding latex is not possible, medications can be taken to reduce symptoms, depending on the type and severity of symptoms.

WWW.BOOKBAZ.IR

Drugs

Patients who have mild reactions can find symptom relief for **itching**, coughing, and a runny nose or eyes from taking **antihistamines**. Nonsteroidal anti-inflammatory medications also can help ease discomfort. Some patients might require use of **steroids**. A person who has severe, anaphylactic shock from latex exposure requires an injection of epinephrine, a synthetic hormone used to treat life-threatening allergic reactions. The doctor might also prescribe an epinephrine injection (EpiPen Auto-Injector), which the patient should keep with them at all times in case there is another latex exposure. Injecting the epinephrine can help treat the anaphylactic reaction quickly. Topical steroids might be prescribed for contact dermatitis reactions to latex.

Alternatives

Alternatives to latex are available, but many of them are synthetic products. Butterbur (*Petasites hybrides*) has been touted as an alternative to antihistamines to relieve allergic skin reactions and nasal symptoms. People experiencing anaphylactic shock always should seek immediate medical attention.

Home remedies

Being aware of products that contain or might contain latex can help prevent exposure. Frequent hand-washing also can help prevent latex particles from settling on the hands. Steam can help relieve nasal congestion. Some natural products such as aloe vera or sunflower oil could help ease the discomfort of irritated skin, but it is best to check with a doctor first. People who have severe anaphylactic reactions to latex should seek immediate medical care.

Prognosis

People with latex allergies can lead normal, healthy lives, especially if they learn how to avoid contact with latex. Anaphylaxis can cause death if not treated.

Prevention

Physicians, employers, and occupational agencies can provide education about recognizing latex in materials. The U.S. Food and Drug Administration cautions that labeling products as "latex free" can be misleading, because there is no test to actually determine whether latex is absent in a product. People with latex allergies can look for labels on products to see if they have natural latex rubber and avoid these products. Using powder-free gloves reduces exposure. It also is advised to avoid using oil-based lotions on the hands before wearing rubber gloves. The oils can make the gloves deteriorate.

It is always helpful to wash hands with a mild soap and water after wearing latex gloves and to keep areas that might have latex powder residue cleaned frequently. People who must use latex gloves for their work should use substitutes, such as vinyl or nitrite. People with latex allergies should let others around them know about the allergies. This is especially true for children; parents should let daycare workers and babysitters know about their child's latex allergy. Anyone who has had an anaphylactic reaction to latex should have autoinjectible epinephrine available at all times in case of exposure.

KEY TERMS

Anaphylactic shock—A severe reaction that can be fatal when certain people are exposed to specific substances to which they have allergies or sensitivities. The person develops severe breathing problems, itching, hives, and stomach difficulties and needs immediate medical attention.

Immune system—The body's system that protects it from foreign substances.

Latex—A milky white fluid, or sap, from certain plants that makes up certain rubber products.

Mucous membrane—The thin lining of certain body passages, such as the nose, that protects the passage and secretes mucus, the fluid-like substance that moistens and protects the lining.

Urogenital—Also called genitourinary, the organ systems that are involved in reproduction and excretion.

Laxatives

Definition

Laxatives are products that promote bowel movements.

Purpose

Laxatives are used to treat constipation—the passage of small amounts of hard, dry stools, usually fewer than three times a week. Before recommending the use of laxatives, differential diagnosis is usually performed because prolonged **constipation** may be evidence of a significant problem, such as localized **peritonitis** (an infection of the abdominal wall) or **diverticulitis** (an infection of part of the intestine). Complaints of constipation also may be associated with **obsessive-compulsive disorder**. Use of laxatives should be avoided in these cases. Individuals should be aware that patterns of defecation are highly variable. Normal patterns may vary from two to three times daily to two to three times weekly.

Laxatives may also be used prophylacticly for patients recovering from a myocardial infarction (**heart attack**) or those who have had recent surgery and should not strain during defecation. Laxatives are also used to cleanse the lower bowel before a **colonoscopy** or similar diagnostic imaging procedure.

Description

Laxatives may be grouped by mechanism of action. Saline cathartics include dibasic **sodium** phosphate (Phospo-Soda), magnesium citrate, magnesium hydroxide (milk of magnesia), magnesium sulfate (Epsom salts), and sodium biphosphate. These laxatives act by attracting and holding water in the intestine and may produce a watery stool. Magnesium sulfate is the most potent of the laxatives in this group.

Stimulant and irritant laxatives increase the contracting movements of the intestine, causing stool to move faster through the bowl and giving less time for water to be absorbed. Examples of these laxatives include cascara and bisadocyl (Dulcolax.) Castor oil works in a similar fashion.

Bulk-producing laxatives increase the volume of the stool, soften the stool, and stimulate intestinal motility. Psyllium (Metamucil, Konsil) and methylcellulose (Citrucel) are examples of this type of laxative. The overall effect is similar to that of eating high-fiber foods, and this class of laxative is most suitable for regular use. Many primary care physicians suggest that patients try laxatives in this category before using saline or stimulant laxatives.

Stool softener laxatives causes water to be retained within the fecal mass, providing a larger, softer stool. Docusate (Colace) is a representative example of the stool softener class of laxatives. It must be taken before the fecal mass forms to have any effect, so it has no effect on acute constipation. It may, however, be useful in preventing constipation in patients with recurrent problems or in those who are about to take a constipating drug, such as narcotic **analgesics**.

Mineral oil is an emollient laxative. Emollient laxatives act by retarding intestinal absorption of fecal water and moving the feces more easily through the intestine, thereby softening the stool.

The hyperosmotic laxatives are glycerin and lactulose (Chronulac, Duphalac), both of which act by holding water within the intestine. Lactulose may also increase contractions of the intestine.

Some newer options for the treatment of chronic constipation are being developed by researchers. These include alternative therapies such as **biofeedback**, newer drugs like tegaserod (Zelnorm) and prucalopride, which stimulate peristalsis (muscle contraction in the intestine), a nerve growth factor known as neurotrophin-3, and electrical stimulation of the colon.

Recommended dosage

Dosage varies widely depending on the product and whether constipation is acute or chronic. See specific products or consult a healthcare provider.

WWW.BOOKBAZ.IR

KEY TERMS

Cathartic colon—A poorly functioning colon, resulting from the chronic abuse of stimulant cathartics.

Colon—The large intestine.

Diverticulitis—Inflammation of the part of the intestine known as the diverticulum.

Fiber—Carbohydrate material in food that cannot be digested.

Hyperosmotic—Hypertonic, containing a higher concentration of salts or other dissolved materials than normal tissues.

Osteomalacia—A disease of adults, characterized by softening of the bone. Similar to rickets which is seen in children.

Pregnancy category—A system of classifying drugs according to their established risks for use during pregnancy. Category A: Controlled human studies have demonstrated no fetal risk. Category B: Animal studies indicate no fetal risk, but no human studies, or adverse effects in animals, but not in well-controlled human studies. Category C: No adequate human or animal studies, or adverse fetal effects in animal studies, but no available human data. Category D: Evidence of fetal risk, but benefits outweigh risks. Category X: Evidence of fetal risk. Risks outweigh any benefits.

Steatorrhea—An excess of fat in the stool.

Stool—The solid waste that is left after food is digested. Stool forms in the intestines and passes out of the body through the anus.

Risks

Short-term use of laxatives is generally safe except in patients experiencing **appendicitis**, fecal impaction, or intestinal obstruction. Lactulose is composed of two sugar molecules, galactose and fructose and should not be administered to patients who require a low galactose diet.

Chronic use of laxatives may result in fluid and electrolyte imbalances, steatorrhea, osteomalacia, **diarrhea**, cathartic colon, and **liver disease**. Excessive intake of mineral oil may cause impaired absorption of the oil-soluble **vitamins** A, D, E, and K. Excessive use of magnesium salts may cause hypermagnesemia.

Lactulose and magnesium sulfate are **pregnancy** category B substances, which means that there is no evidence in animals of harm to a fetus from the drug, but no significant studies on humans have been performed. Casanthranol, cascara sagrada, danthron, docusate sodium, docusate **calcium**, docusate potassium, mineral oil and senna are pregnancy category C substances, meaning that either harm to the fetus has been shown in animals or there are no animal studies available, and there are no controlled human studies. Casanthranol, cascara sagrada and danthron are excreted in breast milk, resulting in the potential for increased incidence of diarrhea in a nursing infant.

The American College of Toxicology states that cathartics should *not* be used as a means of clearing poisons from the digestive tract of a **poisoning** victim. Although some physicians have administered these laxatives along with **activated charcoal** in order to reduce the body's absorption of the poison, this treatment is no longer recommended.

Interactions

Mineral oil and docusate should not be used in combination. Docusate is an emulsifying agent that will increase the absorption of mineral oil.

Bisacodyl tablets are enteric coated, and so they should not be used in combination with **antacids**. The antacids will cause premature rupture of the enteric coating. Many medications should not be taken within two hours of taking a laxative. The patient should ask his or her doctor or pharmacist about this and other possible considerations before beginning to take a laxative.

Lead poisoning

Definition

Lead **poisoning** occurs when a person swallows, absorbs, or inhales lead in any form. The result can be damaging to the brain, nerves, and many other parts of the body. Acute lead poisoning, which is somewhat rare, occurs when a relatively large amount of lead is taken into the body over a short period of time. Chronic lead poisoning—a common problem in children—occurs when small amounts of lead are taken in over a longer period. The Centers for Disease Control and Prevention (CDC) defines childhood lead poisoning as a whole-blood lead concentration equal to or greater than 10 micrograms/dL.

Description

Lead can damage almost every system in the human body, and it can also cause high blood pressure (**hypertension**). It is particularly harmful to the developing brain of fetuses and young children. The higher the level of lead in a child's blood, and the longer this elevated level lasts, the greater the chance of ill effects. Over the long term, lead poisoning in a child can lead to learning disabilities, behavioral problems, and even intellectual disabilities (ID). At very high levels, lead poisoning can cause seizures, **coma**, and even death. Most deaths are among males (74%), African Americans (67%), adults over the age of 45 (76%), and Southerners (70%).

About one out of every six children in the United States has a high level of lead in the blood, according to the Agency for Toxic Substances and Disease Registry. Many of these children are exposed to lead through peeling paint in older homes. Others are exposed through dust or soil that has been contaminated by old paint or past emissions of leaded gasoline. Since children between the ages of 12–36 months are apt to put things in their mouths, they are more likely than older children to take in lead. Pregnant women who come into contact with lead can pass it along to the fetus.

More than 80% of American homes built before 1978 have lead-based paint in them, according to the Centers for Disease Control and Prevention (CDC). The older the home, the more likely it is to contain lead paint, and the higher the concentration of lead in the paint is apt to be. Some homes also have lead in the water pipes or plumbing. People may have lead in the paint, dust, or soil around their homes or in their drinking water without knowing it, since lead can not be seen, smelled, or tasted. Because lead does not break down naturally, it can continue to cause problems until it is removed.

Lead poisoning and the broad issue of dangerously high levels of lead in common consumer product, especially those made in China, became a major issue in 2007. The summer of 2007 saw a record number of recalls of millions of toys made in China, primarily because of high levels of lead. Affected were several of the leading United States toy companies. In August 2007, Fisher-Price recalled one million toy products, including popular Sesame Street characters, Dora the Explorer, and Go, Diego, Go. That same month, Mattel recalled millions of toys involving such high-profile brands as Barbie, Sarge die cast cars, Doggie Day Care, and Polly Pocket Play Sets, according to the U.S. Consumer Product Safety Commission. Worldwide, Mattel recalled 18.2 million Chinese-made toys as of September 2007, including nearly 10 million in the United States. In November 2007, at the start of the holiday buying season, Kmart removed jewelry from its stores that had been advertised as lead-free after extremely high concentrations of lead were found in some pieces. In some cases, more than half of the jewelry's content was lead. Kmart refused to say how many pieces were involved or where they were made. In August 2007, two U.S. law firms filed class action lawsuits against Mattel Inc. asking for more than $5 million in damages.

Causes and symptoms

Before scientists knew how harmful it could be, lead was widely used in paint, gasoline, water pipes, and many other products. Today house paint is almost lead-free, gasoline is unleaded, and household plumbing is no longer made with lead materials. Still, remnants of the old hazards remain. Following are some sources of lead exposure:

ALICE HAMILTON (1869–1970)

Alice Hamilton *(courtesy of Library of Congress, George Grantham Bain Collection (Library of Congress), Bain News Service, publisher)*

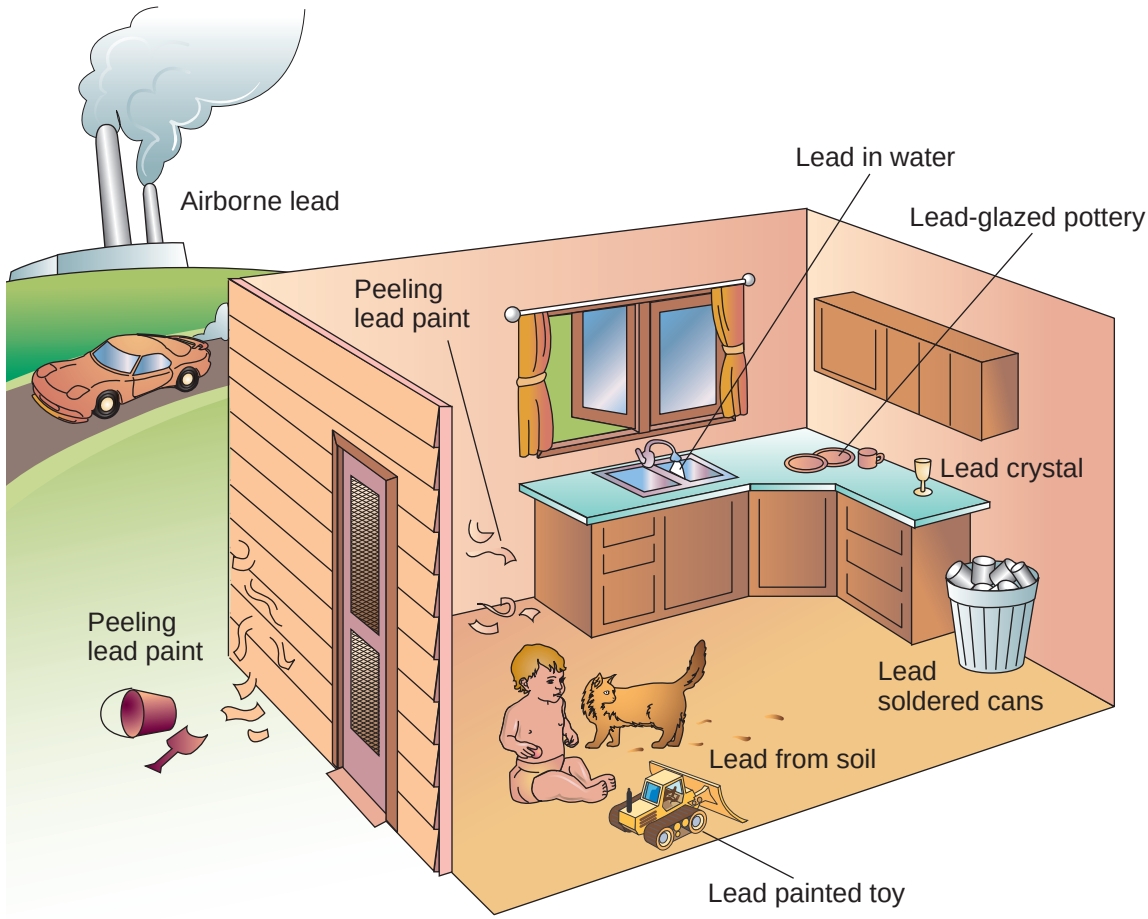
Alice Hamilton was one of the first to associate environmental-related factors with certain illnesses. She noticed unsafe environmental conditions affected people's wellbeing and health. In 1902, during Chicago's typhoid fever epidemic, Hamilton linked the disease to inadequate sewage control. She determined flies, attracted to the sewage, were carrying and transmitting the disease.

In 1910, the governor of Illinois created the Occupational Disease Commission. It was the first of its kind, and he appointed Alice Hamilton director. Hamilton researched the health effects of employee exposure to lead, viscose rayon, and noxious fumes. She found that exposure had grave side effects, including loss of vision, paralysis, and death. Hamilton worked with governmental officials to change unsafe working conditions, campaign against child labor, and pass workers' compensation laws. She gained international attention for her advocacy for the common worker, and was asked by the U.S. Commissioner of Labor to extend her work on a national level. Hamilton accepted this national position, working pro bono, from 1911-1921 when her position was eliminated.

- Lead-based paint. This is the most common source of exposure to large amounts of lead among preschoolers. Children may eat paint chips from older homes that have fallen into disrepair. They may also chew on painted surfaces such as windowsills. In addition, paint may be disturbed during remodeling.
- Dust and soil. These can be contaminated with lead from old paint or past emissions of leaded gasoline. In addition, pollution from operating or abandoned industrial sites and smelters can find its way into the soil, resulting in soil contamination.
- Drinking water. Exposure may come from lead water pipes, found in many homes built before 1930. Even newer copper pipes may have lead solder. Also, some new homes have brass faucets and fittings that can leach lead.
- Jobs and hobbies. A number of activities can expose participants to lead. These include making pottery or stained glass, refinishing furniture, doing home repairs, and using indoor firing ranges. When adults take part in such activities, they may inadvertently expose children to lead residue that is on their clothing or on scrap materials.
- Food. Imported food cans often have lead solder. Lead may also be found in leaded crystal glassware and some imported ceramic or old ceramic dishes (e.g., ceramic dishes from Mexico). A 2003 study of cases of lead poisoning in pregnant women found that 70% of the patients were Hispanics, most of whom had absorbed the lead from their pottery. In addition, food may be contaminated by lead in the water or soil.
- Folk medicines. Certain folk medicines (for example, alarcon, alkohl, azarcon, bali goli, coral, ghasard, greta, liga, pay-loo-ah, and rueda) and traditional cosmetics (kohl, for example) contain large amounts of lead.
- Moonshine whiskey. Lead poisoning from drinking illegally distilled liquor is still a cause of death among adults in the southern United States.
- Gunshot wounds. Toxic amounts of lead can be absorbed from bullets or bullet fragments that remain in the body after emergency surgery.

Chronic lead poisoning

New evidence suggests that lead may be harmful to children even at low levels that were once thought to be safe, and the risk of damage rises as blood levels of



Continuous exposure to lead can damage nearly every system in the human body and is particularly harmful to the developing brain of fetuses and young children. Common sources of lead exposure include lead-based paint, dust and soil, drinking water, food from cans, and eating utensils, such as plates and drinking glasses, that are lead-based. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

lead increase. The symptoms of chronic lead poisoning take time to develop, however. Children can appear healthy despite having high levels of lead in their blood. Over time, though, problems such as the following may arise:

- learning disabilities
- hyperactivity
- intellectual disabilities
- slowed growth
- hearing loss
- headaches

It is also known that certain genetic factors increase the harmful effects of lead poisoning in susceptible children; however, these factors are not completely understood.

Lead poisoning is also harmful to adults, in whom it can cause high blood pressure, digestive problems, nerve disorders, **memory loss**, and muscle and joint **pain**. In addition, it can lead to difficulties during **pregnancy**, as well as cause reproductive problems in men and women.

More recently, chronic exposure to lead in the environment has been found to speed up the progression of kidney disorders in patients without diabetes.

Acute lead poisoning

Acute lead poisoning, while less common, shows up more quickly and can be fatal. Symptoms such as the following may occur:

- severe abdominal pain
- diarrhea

WWW.BOOKBAZ.IR

- nausea and vomiting
- weakness of the limbs
- seizures
- coma

Diagnosis

A high level of lead in the blood can be detected with a simple blood test. In fact, testing is the only way to know for sure if children without symptoms have been exposed to lead, since they can appear healthy even as long-term damage occurs. The CDC recommends testing all children at 12 months of age and, if possible, again at 24 months. Testing should start at six months for children at risk for lead poisoning. Based on these test results and a child's risk factors, the doctor will then decide whether further testing is needed and how often. In some states, more frequent testing is required by law.

Children at risk

Children with an increased risk of lead poisoning include those who:

- Live in or regularly visit a house built before 1978 in which chipped or peeling paint is present.
- Live in or regularly visit a house that was built before 1978 where remodeling is planned or underway.
- Have a brother or sister, housemate, or playmate that has been diagnosed with lead poisoning.
- Have the habit of eating dirt, or have been diagnosed with pica.
- Live with an adult whose job or hobby involves exposure to lead.
- Live near an active lead smelter, battery-recycling plant, or other industry that can create lead pollution.

Adults at risk

Testing is also important for adults whose job or hobby puts them at risk for lead poisoning. This includes people who take part in the following activities:

- glazed pottery or stained glass making
- furniture refinishing
- home renovation
- target shooting at indoor firing ranges
- battery reclamation
- precious metal refining
- radiator repair
- art restoration

Treatment

The first step in treating lead poisoning is to avoid further contact with lead. For adults, this usually means making changes at work or in hobbies. For children, it means finding and removing sources of lead in the home. In most states, the **public health** department can help assess the home and identify lead sources.

If the problem is lead paint, a professional with special training should remove it. Removal of lead paint is not a do-it-yourself project. Scraping or sanding lead paint creates large amounts of dust that can poison people in the home. This dust can stay around long after the work is completed. In addition, heating lead paint can release lead into the air. For these reasons, lead paint should only be removed by someone who knows how to do the job safely and has the equipment to clean up thoroughly. Occupants, especially children and pregnant women, should leave the home until the cleanup is finished.

Medical professionals should take all necessary steps to remove bullets or bullet fragments from patients with gunshot injuries.

Chelation therapy

If blood levels of lead are high enough, the doctor may also prescribe **chelation therapy**. This refers to treatment with chemicals that bind to the lead and help the body pass it in urine at a faster rate. There are four chemical agents that may be used for this purpose, either alone or in combination. Edetate **calcium** disodium (EDTA calcium) and dimercaprol (BAL) are given through an intravenous line or in shots, while succimer (Chemet) and penicillamine (Cuprimine, Depen) are taken by mouth. (Although many doctors prescribe penicillamine for lead poisoning, this use of the drug has not been approved by the Food and Drug Administration.)

Alternatives

Changes in diet are no substitute for medical treatment. However, getting enough calcium, zinc, and protein may help reduce the amount of lead the body absorbs. Iron is also important, since people who are deficient in this nutrient absorb more lead. Garlic and thiamine, a B-complex vitamin, have been used to treat lead poisoning in animals. However, their usefulness in humans for this purpose has not been proved. Nutritional, botanical, and homeopathic medicines can be administered once the source is removed, to help correct any imbalances brought on by lead toxicity.

KEY TERMS

Chelation therapy—Treatment with chemicals that bind to a poisonous metal and help the body pass it in urine at a faster rate.

Dimercaprol (BAL)—A chemical agent used to remove excess lead from the body.

Edetate calcium disodium (EDTA calcium)—A chemical agent used to remove excess lead from the body.

Penicillamine (Cuprimine, Depen)—A drug used to treat medical problems (such as excess copper in the body and rheumatoid arthritis) and to prevent kidney stones. It is also sometimes prescribed to remove excess lead from the body.

Pica—An abnormal appetite or craving for non-food items, often such substances as chalk, clay, dirt, laundry starch, or charcoal.

Succimer (Chemet)—A drug used to remove excess lead from the body.

Prognosis

If acute lead poisoning reaches the stage of seizures and coma, there is a high risk of death. Even if the person survives, there is a good chance of permanent brain damage. The long-term effects of lower levels of lead can also be permanent and severe. However, if chronic lead poisoning is caught early, these negative effects can be limited by reducing future exposure to lead and getting proper medical treatment.

Prevention

Many cases of lead poisoning can be prevented. These steps can help:

- Keep the areas where children play as clean and dust-free as possible.
- Wash pacifiers and bottles when they fall to the floor, and wash stuffed animals and toys often.
- Make sure children wash their hands before meals and at bedtime.
- Mop floors and wipe windowsills and other chewable surfaces, such as cribs, twice a week with a solution of powdered dishwasher detergent in warm water.
- Plant bushes next to an older home with painted exterior walls to keep children at a distance.
- Plant grass or another ground cover in soil that is likely to be contaminated, such as soil around a home built before 1960 or located near a major highway.
- Have household tap water tested to find out if it contains lead.
- Use only water from the cold-water tap for drinking, cooking, and making baby formula, since hot water is likely to contain higher levels of lead.
- If the cold water hasn't been used for six hours or more, run it for several seconds, until it becomes as cold as it will get, before using it for drinking or cooking. The more time water has been sitting in the pipes, the more lead it may contain.
- If you work with lead in your job or hobby, change your clothes before you go home.
- Do not store food in open cans, especially imported cans.
- Do not store or serve food in pottery meant for decorative use.

Learning disorders

Definition

Learning disorders are academic difficulties experienced by children and adults of average to above-average intelligence. People with learning disorders have difficulty with reading, writing, mathematics, or a combination of the three. These difficulties significantly interfere with academic achievement or daily living.

Description

Learning disorders, or disabilities, affect approximately 2 million children between the ages of six and 17 (5% of public school children), although some experts think the figure may be as high as 15%. These children have specific impairments in acquiring, retaining, and processing information. Standardized tests place them well below their IQ range in their area of difficulty. The three main types of learning disorders are reading disorders, mathematics disorders, and disorders of written expression. The male: female ratio for learning disorders is about 5:1.

Reading disorders

Reading disorders are the most common type of learning disorder. Children with reading disorders have difficulty recognizing and interpreting letters and words (**dyslexia**). They aren't able to recognize and decode the sounds and syllables (phonetic structure) behind written words and language in general. This condition lowers accuracy and comprehension in reading.

Mathematics disorders

Children with mathematics disorders (dyscalculia) have problems recognizing and counting numbers correctly. They have difficulty using numbers in everyday settings. Mathematics disorders are typically diagnosed in the first few years of elementary school when formal teaching of numbers and basic math concepts begins. Children with mathematics disorders usually have a co-existing reading disorder, a disorder of written expression, or both.

Disorders of written expression

Disorders of written expression typically occur in combination with reading disorders or mathematics disorders or both. The condition is characterized by difficulty with written compositions (dysgraphia). Children with this type of learning disorder have problems with spelling, punctuation, grammar, and organizing their thoughts in writing.

Causes and symptoms

Learning disorders are thought to be caused by neurological abnormalities that trigger impairments in the regions of the brain that control visual and language processing and attention and planning. These traits may be genetically linked. Children from families with a history of learning disorders are more likely to develop disorders themselves. In 2003 a team of Finnish researchers reported finding a candidate gene for developmental dyslexia on human chromosome 15q21.

Learning difficulties may also be caused by such medical conditions as a **traumatic brain injury** or brain infections such as encephalitis or **meningitis**.

The defining symptom of a learning disorder is academic performance that is markedly below a child's age and grade capabilities and measured IQ. Children with a reading disorder may confuse or transpose words or letters and omit or add syllables to words. The written homework of children with disorders of written expression is filled with grammatical, spelling, punctuation, and organizational errors. The child's handwriting is often extremely poor. Children with mathematical disorders are often unable to count in the correct sequence, to name numbers, and to understand numerical concepts.

Diagnosis

Problems with vision or hearing, mental disorders (depression, attention-deficit/hyperactivity disorder), intellectual disabilities (ID), cultural and language differences, and inadequate teaching may be mistaken for learning disorders or complicate a diagnosis. A comprehensive medical, psychological, and educational assessment is critical to making a clear and correct diagnosis.

A child thought to have a learning disorder should undergo a complete medical examination to rule out an organic cause. If none is found, a psychoeducational assessment should be performed by a psychologist, psychiatrist, neurologist, neuropsychologist, or learning specialist. A complete medical, family, social, and

educational history is compiled from existing medical and school records and from interviews with the child and the child's parents and teachers. A series of written and verbal tests are then given to the child to evaluate his or her cognitive and intellectual functioning. Commonly used tests include the Wechsler Intelligence Scale for Children (WISC-III), the Woodcock-Johnson Psychoeducational Battery, the Peabody Individual Achievement Test-Revised (PIAT-R) and the California Verbal Learning Test (CVLT). Federal legislation mandates that this testing is free of charge within the public school system.

Treatment

Once a learning disorder has been diagnosed, an individual education plan (IEP) is developed for the child in question. IEPs are based on psychoeducational test findings. They provide for annual retesting to measure a child's progress. Learning-disordered students may receive special instruction within a regular general education class or they may be taught in a special education or learning center for a portion of the day.

Common strategies for the treatment of reading disorders focus first on improving a child's recognition of the sounds of letters and language through phonics training. Later strategies focus on comprehension, retention, and study skills. Students with disorders of written expression are often encouraged to keep journals and to write with a computer keyboard instead of a pencil. Instruction for students with mathematical disorders emphasizes real-world uses of arithmetic, such as balancing a checkbook or comparing prices.

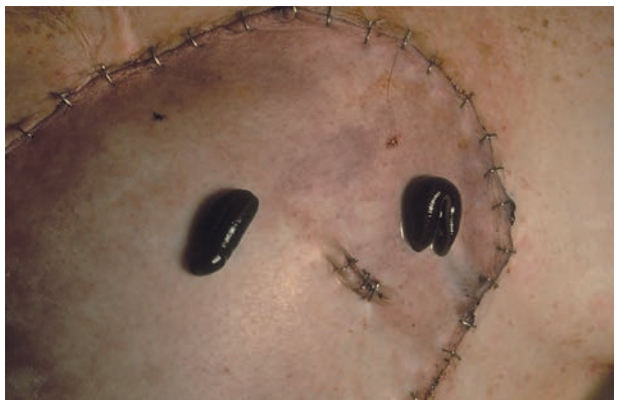
Leeches

Definition

Leeches are bloodsucking worms with segmented bodies. They belong to the same large classification of worms as earthworms and certain oceanic worms.

Leeches can primarily be found in freshwater lakes, ponds, or rivers. They range in size from 0.2 in

WWW.BOOKBAZ.IR



These leeches are being used to reduce venous congestion, or excessive amounts of blood in the blood vessels. *(Custom Medical Stock Photo, Inc.)*

(5 mm) to nearly 18 in (45 cm) and have two characteristic suckers located at either end of their bodies. Leeches consume the blood of a wide variety of animal hosts, ranging from fish to humans. To feed, a leech first attaches itself to the host using the suckers. One of these suckers surrounds the leech's mouth, which contains three sets of jaws that bite into the host's flesh, making a Y-shaped incision. As the leech begins to feed, its saliva releases chemicals that dilate blood vessels, thin the blood, and deaden the **pain** of the bite. Because of the saliva's effects, a person bitten by a leech may not even be aware of it until afterwards, when he or she sees the incision and the trickle of blood that is difficult to stop.

For centuries, leeches were a common tool of doctors, who believed that many diseases were the result of "imbalances" in the body that could be stabilized by releasing blood. For example, leeches were sometimes attached to veins in the temples to treat headaches. Advances in medical knowledge led doctors to abandon bloodletting and the use of leeches in the mid-nineteenth century. In recent years, however, doctors have found a new purpose for leeches—helping to restore blood circulation to grafted or severely injured tissue.

Purpose

There are many occasions in medicine, mostly in surgery and **trauma** care, when blood accumulates and causes trouble. Leeches can be used to reduce the swelling of any tissue that is holding too much blood. This problem is most likely to occur in two situations:

- Trauma. Large blood clots resulting from trauma can threaten tissue survival by their size and pressure. Blood clots can also obstruct the patient's airway.
- Surgical procedures involving reattachment of severed body parts or tissue reconstruction following burns. In these situations it is difficult for the surgeon to make a route for blood to leave the affected part and return to the circulation. The hardest part of reattaching severed extremities like fingers, toes and ears is to reconnect the tiny veins. If the veins are not reconnected, blood will accumulate in the injured area. A similar situation occurs when plastic surgeons move large flaps of skin to replace skin lost to burns, trauma or radical surgery. The skin flaps often drain blood poorly, get congested, and begin to die. Leeches have come to the rescue in both situations.

Precautions

It is important to use only leeches that have been raised in the laboratory under sterile conditions in order to protect patients from infection. Therapeutic leeches belong to one of two species–*Hirudo michaelseni* or *Hirudo medicinalis*.

Description

One or more leeches are applied to the swollen area, depending on the size of the graft or injury, and left on for several hours. The benefits of the treatment lie not in the amount of blood that the leeches ingest, but in the anti-bloodclotting (anticoagulant) enzymes in the saliva that allow blood to flow from the bite for up to six hours after the animal is detached, effectively draining away blood that could otherwise accumulate and cause tissue death. Leech saliva has been described as a better anticoagulant than many currently available to treat strokes and heart attacks. Active investigation of the chemicals in leech saliva is currently under way, and one anticoagulant drug, hirudin, is derived from the tissues of *Hirudo medicinalis*.

Aftercare

The leeches are removed by pulling them off or by loosening their grip with cocaine, heat, or acid. The used leeches are then killed by placing them in an alcohol solution and disposed of as a biohazard. Proper care of the patient's sore is important, as is monitoring the rate at which it bleeds after the leech is removed. Any clots that form at the wound site during treatment should be removed to ensure effective blood flow.

Risks

Infection is a constant possibility until the sore heals. It is also necessary to monitor the amount of

Legionnaires' disease

Definition

Legionnaires' disease is a type of **pneumonia** caused by *Legionella* bacteria. The bacterial species responsible for Legionnaires' disease is *L. pneumophila*. Major symptoms include **fever**, chills, muscle aches, and a **cough** that is initially nonproductive. Definitive diagnosis relies on specific laboratory tests for the bacteria, bacterial antigens, or antibodies produced by the body's immune system. As with other types of pneumonia, Legionnaires' disease poses the greatest threat to people who are elderly, ill, or immunocompromised.

Description

Legionella bacteria were first identified as a cause of pneumonia in 1976, following an outbreak of pneumonia among people who had attended an American Legion convention in Philadelphia, Pennsylvania. This eponymous outbreak prompted further investigation into *Legionella* and it was discovered that earlier unexplained pneumonia outbreaks were linked to the bacteria. The earliest cases of Legionnaires' disease were shown to have occurred in 1965, but samples of the bacteria exist from 1947.

Exposure to the *Legionella* bacteria doesn't necessarily lead to infection. According to some studies, an estimated 5–10% of the American population show serologic evidence of exposure, the majority of whom do not develop symptoms of an infection. *Legionella* bacteria account for 2–15% of the total number of pneumonia cases requiring hospitalization in the United States.

There are at least 40 types of *Legionella* bacteria, half of which are capable of producing disease in humans. A disease that arises from infection by *Legionella* bacteria is referred to as legionellosis. The *L. pneumophila bacterium*, the root cause of Legionnaires' disease, causes 90% of legionellosis cases. The second most common cause of legionellosis is the *L. micdadei* bacterium, which produces the Philadelphia pneumonia-causing agent.

Approximately 10,000–40,000 people in the United States develop Legionnaires' disease annually. The people who are the most likely to become ill are over age 50. The risk is greater for people who suffer from health conditions such as malignancy, diabetes, lung disease, or **kidney disease**. Other risk factors include immunosuppressive therapy and cigarette **smoking**. Legionnaires' disease has occurred in children, but typically it has been confined to newborns receiving **respiratory therapy**, children who have had recent operations, and children who are immunosuppressed. People with HIV infection and **AIDS** do not seem to contract Legionnaires' disease with any greater frequency than the rest of the population, however, if contracted, the disease is likely to be more severe compared to other cases.

Cases of Legionnaires' disease that occur in conjunction with an outbreak, or epidemic, are more likely to be diagnosed quickly. Early diagnosis aids effective and successful treatment. During epidemic outbreaks, fatalities have ranged from 5% for previously healthy individuals to 24% for individuals with underlying illnesses. Sporadic cases (that is, cases unrelated to a wider outbreak) are harder to detect and treatment may be delayed pending an accurate diagnosis. The overall fatality rate for sporadic cases ranges from 10–19%. The outlook is bleaker in severe cases that require respiratory support or dialysis. In such cases, fatality may reach 67%.

A transmission electron microscopy (TEM) image of *Legionella pneumophila*, the bacteria that causes Legionnaires' disease. *(Custom Medical Stock Photo, Inc.)*

Causes and symptoms

Legionnaires' disease is caused by inhaling *Legionella* bacteria from the environment. Typically, the bacteria are dispersed in aerosols of contaminated water. These aerosols are produced by devices in which warm water can stagnate, such as air-conditioning cooling towers, humidifiers, shower heads, and faucets. There have also been cases linked to whirlpool spa baths and water misters in grocery store produce departments. Aspiration of contaminated water is also a potential source of infection, particularly in hospital-acquired cases of Legionnaires' disease. There is no evidence of person-to-person transmission of Legionnaires' disease.

Once the bacteria are in the lungs, cellular representatives of the body's immune system (alveolar macrophages) congregate to destroy the invaders. The typical macrophage defense is to phagocytose the invader and demolish it in a process analogous to swallowing and digesting it. However, the *Legionella* bacteria survive being phagocytosed. Instead of being destroyed within the macrophage, they grow and replicate, eventually killing the macrophage. When the macrophage dies, many new *Legionella* bacteria are released into the lungs and worsen the infection.

Legionnaires' disease develops 2–10 days after exposure to the bacteria. Early symptoms include lethargy, headaches, fever, chills, muscle aches, and a lack of appetite. Respiratory symptoms such as coughing or congestion are usually absent. As the disease progresses, a dry, hacking cough develops and may become productive after a few days. In about a third of Legionnaires' disease cases, blood is present in the sputum. Half of the people who develop Legionnaires' disease suffer **shortness of breath** and a third complain of breathing-related chest **pain**. The fever can become quite high, reaching 104°F (40°C) in many cases, and may be accompanied by a decreased heart rate.

Although the pneumonia affects the lungs, Legionnaires' disease is accompanied by symptoms that affect other areas of the body. About half the victims experience **diarrhea** and a quarter have **nausea and vomiting** and abdominal pain. In about 10% of cases, acute renal failure and scanty urine production accompany the disease. Changes in mental status, such as disorientation, confusion, and **hallucinations**, also occur in about a quarter of cases.

In addition to Legionnaires' disease, *L. pneumophila* legionellosis also includes a milder disease, Pontiac fever. Unlike Legionnaires' disease, Pontiac fever does not involve the lower respiratory tract. The symptoms usually appear within 36 hours of exposure and include fever, **headache**, muscle aches, and lethargy. Symptoms last only a few days and medical intervention is not necessary.

Diagnosis

The symptoms of Legionnaires' disease are common to many types of pneumonia and diagnosis of sporadic cases can be difficult. The symptoms and chest x rays that confirm a case of pneumonia are not useful in differentiating between Legionnaires' disease and other pneumonias. If a pneumonia case involves multisystem symptoms, such as diarrhea and **vomiting**, and an initially dry cough, laboratory tests are done to definitively identify *L. pneumophila* as the cause of the infection.

If Legionnaires' disease is suspected, several tests are available to reveal or indicate the presence of *L. pneumophila* bacteria in the body. Since the immune system creates antibodies against infectious agents, examining the blood for these indicators is a key test. The level of immunoglobulins, or antibody molecules, in the blood reveals the presence of infection. In microscopic examination of the patient's sputum, a fluorescent stain linked to antibodies against *L. pneumophila* can uncover the presence of the bacteria. Other means of revealing the bacteria's presence from patient sputum samples include isolation of the organism on culture media or detection of the bacteria by DNA probe. Another test detects *L. pneumophila* antigens in the urine.

Treatment

Most cases of *Legionella* pneumonia show improvement within 12–48 hours of starting antibiotic therapy.

KEY TERMS

Antibody—A molecule created by the immune system in response to the presence of an antigen. It serves to recognize the invader and help defend the body from infection.

Antigen—A molecule, such as a protein, which is associated with a particular infectious agent. The immune system uses this molecule as the identifying characteristic of the infectious invader.

Culture—A laboratory system for growing bacteria for further study.

DNA probe—An agent that binds directly to a predefined sequence of nucleic acids.

Immunocompromised—Refers to conditions in which the immune system is not functioning properly and cannot adequately protect the body from infection.

Immunoglobulin—The protein molecule that serves as the primary building block of antibodies.

Immunosuppressive therapy—Medical treatment in which the immune system is purposefully thwarted. Such treatment is necessary, for example, to prevent organ rejection in transplant cases.

Legionellosis—A disease caused by infection with a Legionella bacterium.

Media—Substance which contains all the nutrients necessary for bacteria to grow in a culture.

Phagocytosis—The "ingestion" of a piece of matter by a cell.

The antibiotic of choice has been erythromycin, sometimes paired with a second antibiotic, rifampin. Tetracycline, alone or with rifampin, is also used to treat Legionnaires' disease, but has had more mixed success in comparison to erythromycin. Other **antibiotics** that have been used successfully to combat *Legionella* include doxycycline, clarithromycin, fluorinated quinolones, and trimethoprim/sulfamethoxazole.

The type of antibiotic prescribed by the doctor depends on several factors including the severity of infection, potential **allergies**, and interaction with previously prescribed drugs. For example, erythromycin interacts with warfarin, a blood thinner. Several drugs, such as **penicillins** and **cephalosporins**, are ineffective against the infection. Although they may be deadly to the bacteria in laboratory tests, their chemical structure prevents them from being absorbed into the areas of the lung where the bacteria are present.

In severe cases with complications, antibiotic therapy may be joined by respiratory support. If renal failure occurs, dialysis is required until renal function is recovered.

Prognosis

Appropriate medical treatment has a major impact on recovery from Legionnaires' disease. Outcome is also linked to the victim's general health and absence of complications. If the patient survives the infection, recovery from Legionnaires' disease is complete. Similar to other types of pneumonia, severe cases of Legionnaires' disease may cause scarring in the lung tissue as a result of the infection. Renal failure, if it occurs, is reversible and renal function returns as the patient's health improves. Occasionally, **fatigue** and weakness may linger for several months after the infection has been successfully treated.

Prevention

Since the bacteria thrive in warm stagnant water, regularly disinfecting ductwork, pipes, and other areas that may serve as breeding areas is the best method for preventing outbreaks of Legionnaires' disease. Most outbreaks of Legionnaires' disease can be traced to specific points of exposure, such as hospitals, hotels, and other places where people gather. Sporadic cases are harder to determine and there is insufficient evidence to point to exposure in individual homes.

Leishmaniasis

Definition

Leishmaniasis refers to several different illnesses caused by infection with a parasitic organism called a protozoan. Specifically, the organism belongs to the genus *Leishmania*. The disease is transmitted to humans from certain species of the infected female

sand fly (order Dipteran) that are found in sandy areas. In the United States, the sand fly is often referred to by the terms of horse fly, greenhead, sand flea, sand gnats, and various others. In the Balkans the sand fly is called the Balkan sore; in India, the Delhi boil; and in Iraq the Baghdad boil; while in Afghanistan it is called saldana.

Demographics

All ages of people are susceptible to the disease. However, children are at greater risk than are adults. In addition, it is more common in rural areas than in urban settings. The disease is also of greater risk to men than it is to women, probably because males tend to be outside more frequently than females and are more likely to be exposed to sand flies at a higher rate. The risk of getting the disease is higher during nighttime because sand flies are more active in darkness then in sunlight. People also at heightened risk for the disease are adventure travelers, ecotourists, and other tourists visiting areas where leishmaniasis is more common. Volunteers, missionaries, soldiers in such areas where the disease is common are also at higher risk, as are bird watchers, ornithologists (people who study birds), and people who frequently work and play outside.

Medical studies have shown that people with acquired immune deficiency syndrome (**AIDS**) have a 100 to 1,000 greater chance of developing visceral leishmaniasis, one of the four primary types of leishmaniasis.

The disease is found primarily in the tropics, subtropics, and southern Europe. In the Western Hemisphere, it is found in parts of Mexico, Central America, and South America (but not in Chile or Uruguay). In the Eastern Hemisphere, it is frequently located in parts of Asia, the Middle East, southern Europe, and Africa.

At any one time, about 12 to 20 million people throughout the world are infected with leishmaniasis. According to the U.S. Centers for Disease Control and Prevention (CDC), about 1.5 million new cases of cutaenous leishmaniasis, the most common type of the disease, are reported yearly worldwide, while about a half million new cases of visceral leishmaniasis, the second most common type, are estimated annually. It is estimated that over 80,000 deaths occur annually from the disease.

While leishmaniasis exists as a disease in about 88 countries on five continents, some countries are hit harder than others. The vast majority of cases of cutaneous leishmaniasis take place in Afghanistan, Algeria, Brazil, Iran, Iraq, Peru, Saudi Arabia, and Syria. Almost all of the cases of visceral leishmaniasis happen in Bangladesh, Brazil, India, Nepal, and Sudan. Other areas that harbor the causative protozoa include China, many countries throughout Africa, Mexico, Central and South America, Turkey, and Greece. Cases of leishmaniasis occur in the United States but only from people who have traveled outside of the country. In addition, cases of cutaneous leishmaniasis have taken place in Texas and Oklahoma. Past cases of visceral leishmaniasis have not been reported in the United States, according to the CDC.

Description

Protozoa are considered to be the most simple organisms in the animal kingdom. They are all single-celled. The blood-sucking sand fly carries the types of protozoa that cause leishmaniasis. The sand fly is referred to as the disease vector, simply meaning that the infectious agent (the protozoan) is transported by the sand fly and passed on to other animals or humans in whom the protozoan will set up residence and cause disease. The animal or human in which the protozoan then resides is referred to as the host.

Once the protozoan is within the human host, the human's immune system is activated to try to combat the invader. Specialized immune cells called macrophages work to swallow up the protozoa. Usually, this technique kills a foreign invader, but these protozoa can survive and flourish within macrophages. The protozoa multiply within the macrophages, ultimately causing the macrophage to burst open. The protozoa are released, and take up residence within other neighboring cells.

At this point, the course of the disease caused by the protozoa is dependent on the specific type of protozoa, and on the type of reaction the protozoa elicits from the immune system. There are several types of protozoa that cause leishmaniasis, and they produce different patterns of disease progression.

There are four primary types of leishmaniasis. They are:

- Localized (simple) cutaneous leishmaniasis, which is the most common type, causes a skin sore at the site of the bite. This type can then proceed to become any of the other three types.
- Diffuse cutaneous leishmaniasis, which is difficult to treat, can produce large areas of skin lesions that resemble leprosy.
- Mucocutaneous leishmaniasis, which starts with skin ulcers, is especially troublesome for the nose and mouth.
- Visceral leishmaniasis, which is the second most common type and the most serious one because it usually affects some of the internal organs (such as liver and spleen), can be fatal if not treated promptly.

Causes and symptoms

There are a number of types of protozoa that can cause leishmaniasis. Each type exists in specific locations, and there are different patterns to the kind of disease each causes. The overall species name is Leishmania (commonly abbreviated L.). The specific types include: *L. Donovani, L. Infantum, L. Chagasi, L. Mexicana, L. Amazonensis, L. Tropica, L. Major, L. Aethiopica, L. Brasiliensis, L. Guyaensis, L. Panamensis, L. Peruviana*. Some of the names are reflective of the locale in which the specific protozoa is most commonly found, or in which it was first discovered.

Localized cutaneous leishmaniasis

This type of disease, also called simple cutaneous leishmaniasis, occurs most commonly in China, India, Asia Minor, Africa, the Mediterranean Basin, and Central America. It has ranged in an area from northern Argentina all the way up to southern Texas. It is called different names in different locations, including chiclero ulcer, bush **yaws**, uta, oriental sore, Aleppo boil, and Baghdad sore.

This is perhaps the least drastic type of disease caused by any of the *Leishmania*. Several weeks or months after being bitten by an infected sand fly, the host may notice an itchy bump (lesion) on an arm, leg, or face. Lymph nodes in the area of this bump may be swollen. Within several months, the bump develops a crater (ulceration) in the center, with a raised, reddened ridge around it. There may be several of these lesions (sores) near each other, and they may spread into each other to form one large lesion. Often, individual lesions change in size and appearance as they develop. Eventually, they may have a raised edge and a central ulcerated area. People with sores also often have **swollen glands** near the infected areas. Although localized cutaneous leishmaniasis usually heals on its own, it may take as long as one year. A depressed, light-colored scar usually remains behind. Some lesions never heal, and may invade and destroy the tissue below. For example, lesions on the ears may slowly, but surely, invade and destroy the cartilage that supports the outer ear.

Diffuse cutaneous leishmaniasis

This type of disease occurs most often in Ethiopia, Brazil, Dominican Republic, and Venezuela.

The lesions of diffuse cutaneous leishmaniasis are very similar to those of localized cutaneous leishmaniasis, except they are spread all over the body. The body's immune system apparently fails to battle the protozoa, which are free to spread throughout. The characteristic lesions resemble those of the dread biblical disease, **leprosy**.

Mucocutaneous leishmaniasis

This type of leishmaniasis occurs primarily in the tropics of South America.

With an incubation period of from one to three months, the disease begins with the same sores noted in localized cutaneous leishmaniasis. Sometimes these primary lesions heal, other times they spread and become larger. Some years after the first lesion is noted (and sometimes several years after that lesion has totally healed), new lesions appear in the mouth and nose, and occasionally in the area between the genitalia and the anus (the perineum). These new lesions, called mucosal lesions, are particularly destructive and painful. Sometimes their appearance is delayed twenty years from the first presence of the primary lesions.

The mucosal lesions erode underlying tissue and cartilage, frequently eating through the septum (the cartilage that separates the two nostrils). If the lesions spread to the roof of the mouth and the larynx (the part of the wind pipe which contains the vocal cords), they may prevent speech. Other symptoms include **fever**, weight loss, and anemia (low red blood cell count). There is always a large danger of bacteria infecting the already open sores.

WWW.BOOKBAZ.IR

Visceral leishmaniasis

This type of leishmaniasis occurs in India, China, the southern region of Russia, and throughout Africa, the Mediterranean, and South and Central America. It is frequently called Kala-Azar or Dumdum fever.

In this disease, the protozoa use the bloodstream to travel to the liver, spleen, lymph nodes, and bone marrow. Fever may last for as long as eight weeks, disappear, and then reappear again. The lymph nodes, spleen, and liver are often quite enlarged. Weakness, **fatigue**, loss of appetite, **diarrhea**, and weight loss are common. Abnormal blood tests also result, including low red blood cell count, low **white blood cell count**, and low **platelet count**. Kala-azar translates (from the country of India) to mean "black fever." The name kala-azar comes from a characteristic of this type of leishmaniasis. Individuals with light-colored skin take on a darker, grayish skin tone, particularly of their face and hands. A variety of lesions appear on the skin.

Diagnosis

Diagnosis for each of these types of leishmaniasis involves taking a scraping from a lesion, preparing it in a laboratory, and examining it under a microscope to demonstrate the causative protozoan. Other methods that have been used include:

- Culturing a sample piece of tissue in a laboratory to allow the protozoa to multiply for easier microscopic identification.
- Injecting a mouse or hamster with a solution made of scrapings from a patient's lesion to see if the animal develops a leishmaniasis-like disease.
- Demonstrating the presence in macrophages of the characteristic-appearing protozoan, called Leishman-Donovan bodies.

In some types of leishmaniasis, a skin test (similar to that given for **tuberculosis**, or TB) may be used. In this test, a solution containing a small bit of the protozoan antigen (cell marker that causes the human immune system to react) is injected or scratched into a patient's skin. In a positive reaction, cells from the immune system will race to this spot, causing a characteristic skin lesion. Not all types of leishmaniasis cause a positive skin test, however. The CDC states that diagnosis of leishmaniasis can be difficult. Results from laboratory tests frequently come back as negative even when the person has the disease.

Treatment

The treatment of choice for all types of leishmaniasis is a type of drug containing the element antimony. These include **sodium** sitogluconate, and meglumin antimonate. When these types of drugs do not work, other medications with anti-protozoal activity are utilized, including amphotericin B, pentamidine, flagyl, and allopurinol. In 2004, it was reported that the world's first non-profit drug company was seeking approval in India for a drug to cure visceral leishmaniasis. Historically, an estimated 200,000 people die annually from the disease in that country. The company, called One World Health, hoped to offer the drug called paromomycin for a three-week treatment course. In 2006, paromomycin was approved by the Drug Controller General of India for treatment of visceral leishmaniasis.

Prognosis

The prognosis for leishmaniasis is quite variable, and depends on the specific strain of infecting protozoan, as well as the individual patient's immune system response to infection. Localized cutaneous leishmaniasis may not require any treatment. Although it may take many months, these lesions usually heal themselves completely. Only rarely do these lesions fail to heal and become more destructive.

Diffuse cutaneous leishmaniasis may smolder on for years without treatment, eventually progressing to mucocutaneous leishmaniasis, and ultimately causing death when the large, open lesions become infected with bacteria.

Mucocutaneous leishmaniasis is often relatively resistant to treatment. Untreated visceral leishmaniasis has a 90% death rate, but only a 10% death rate with proper treatment.

Visceral leishmaniasis has been increasingly associated with human **immunodeficiency** virus (HIV). For example, the two have appeared together in southern Europe, primarily among intravenous drug users. If treated properly, the risk from death is minimal. However, the rates of mortality in untreated cases has been shown to range from 75% to 95%. Even when death does not occur from the disease, it can leave the person disfigured and with serious deformities. Advanced cases of visceral leishmaniasis can eventually cause death if left untreated.

Prevention

Prevention involves protecting against sand fly bites. Insect repellents used around homes, on clothing, on skin, and on bed nets (to protect people while sleeping) are effective measures.

KEY TERMS

Host—The organism (such as a monkey or human) in which another organism (such as a virus or bacteria) is living.

Larynx—The part of the airway lying between the pharynx and the trachea.

Leishman-Donovan body—A body of a (trypanosomatid) protozoa at a particular and characteristic stage in its life cycle; the infectious (trypanosomatid) protozoa can cause leishmaniasis, and is relatively easy to identify at that stage.

Lesion—A disruption of the normal structure and function of a tissue by some disease process.

Macrophage—A cell of the immune system that engulfs and digests foreign invaders such as bacteria and viruses in an attempt to stop them from causing disease within the body.

Protozoa—A group of organisms which are the smallest members of the animal kingdom, consisting of a single cell.

Ulceration—An area of pitting and irritation.

Vector—A carrier organism (such as a fly or mosquito) that to delivers a virus (or other agent of infection) to a host.

Reducing the population of sand flies is also an important preventive measure. In areas where leishmaniasis is very common, recommendations include clearing the land of trees and brush for at least 984 feet (300 meters) around all villages, and regularly spraying the area with insecticides. Because rodents often carry the protozoan that causes leishmaniasis, careful rodent control should be practiced. Dogs, which also carry the protozoan, can be given a simple blood test.

Leprosy

Definition

Leprosy is a slowly progressing chronic bacterial infection that affects the skin, peripheral nerves in the hands and feet, upper respiratory tract, and mucous membranes of the nose, throat, and eyes. Destruction of the nerve endings causes the affected areas to lose sensation. Leprosy is a progressive disease; that is, one that takes anywhere from six months to 40 years to develop. If left untreated, it can cause **skin lesions** and inflammatory nodules (granulomas) on the skin and nerves and, ultimately, permanent damage and disfigurement to the skin, nerves, limbs, eyes, and other body parts. It primarily affects the outer extremities such as the eyes, nose, earlobes, hands, testicles (in men), and feet.

Demographics

The World Health Organization (WHO) places the number of identified leprosy cases in the world at 189,018 as of mid 2012. According to WHO, the number of new cases diagnosed in 2012 was 220,810. Ninety-five percent of the new cases reported were diagnosed in 16 countries. According to the Department of Health and Human Services, there are about 6,500 reported cases in the United States (with approximately 3,300 of them requiring active medical intervention) as of 2009. Cases also occur in some areas of the Caribbean. Although it was thought for many years that only humans are affected by the disease, 15% of

wild armadillos in southern Texas and Louisiana have been found to be infected with *M. leprae*.

Description

Leprosy is also known as Hansen's disease after Norwegian physician Gerhard Armauer Hansen (1841–1912), who in 1878 identified the bacillus (rod-shaped bacterium) *Mycobacterium leprae* (*M. leprae*) that causes the disease.

The infection is characterized by abnormal changes of the skin. These changes, called lesions, are at first flat and red. Upon enlarging, they have irregular shapes and a characteristic appearance. The lesions are typically darker in color around the edges with discolored pale centers. Because the organism grows best at lower body temperatures, the leprosy bacillus prefers the skin, the mucous membranes, and the nerves. Infection in the nerves and their eventual destruction leads to sensory loss. The loss of sensation in the fingers and toes increases the risk of injury. Inadequate care causes infection of open **wounds**. **Gangrene** may also follow, resulting in the deformation or death of body tissue.

Because of the disabling deformities associated with it, leprosy has been considered one of the most dreaded diseases since Biblical times (beginning at about 1500 B.C. and ending around A.D. 100), though much of what was called leprosy in the Old Testament most likely was not the same disease. Its victims were often shunned by the community, kept at arm's length, or sent to a leper colony. Many people still have misconceptions about the disease. Contrary to popular belief, it is not highly communicable and is extremely slow to develop. Household contacts of most cases and the medical personnel caring for Hansen's disease patients are not at particular risk. It is very curable, although the treatment is long-term, requiring multiple medications.

Causes and symptoms

The organism that causes leprosy is a rod-shaped bacterium called *Mycobacterium leprae*. This bacterium is related to *Mycobacterium tuberculosis*, the causative agent of **tuberculosis**. *M. leprae* is considered an obligate intracellular bacterium; that is, a bacterium that is able to grow only inside certain human and animal cells. Because special staining techniques involving acids are required to view these bacteria under the microscope, they are referred to as acid-fast bacilli (AFB).

When *Mycobacterium leprae* invades the body, one of two reactions can take place. In tuberculoid leprosy (TT), the milder form of the disease, the body's immune cells attempt to seal off the infection from the rest of the body by surrounding the offending pathogen. Because this response by the immune system occurs in the deeper layers of the skin, the hair follicles, sweat glands, and nerves can be destroyed. As a result, the skin becomes dry and discolored and loses its sensitivity. Involvement of nerves on the face, arms, or legs can cause them to enlarge and to become easily felt by the examining doctor. This finding is highly suggestive of TT. The scarcity of bacteria in this type of leprosy leads to it being referred to as paucibacillary (PB) leprosy. Seventy to eighty percent of all leprosy cases are of the tuberculoid type.

In lepromatous (LL) leprosy, which is the second and more contagious form of the disease, the body's immune system is unable to mount a strong response to the invading organism. Hence, the organism multiplies freely in the skin. This type of leprosy is also called the multibacillary (MB) leprosy, because of the presence of large numbers of bacteria. The characteristic feature of this disease is the appearance of large nodules or lesions all over the body and face. Occasionally, the mucous membranes of the eyes, nose, and throat may be involved. Facial involvement can produce a lion-like appearance (leonine facies). This type of leprosy can lead to blindness, drastic change in voice, or mutilation of the nose. Leprosy can strike anyone; however, children seem to be more susceptible than adults.

The early symptoms of leprosy are not apparent, and they may very slowly develop over many years without much notice. Well-defined skin lesions that are numb are the first symptoms of tuberculoid leprosy. Numbness and a decreasing ability to sense hot and cold temperatures are two other early symptoms of leprosy. Lepromatous leprosy is characterized by a chronic stuffy nose due to invasion of the mucous membranes, and the presence of nodules and lesions all over the body and face. As the disease advances, the sense of touch, **pain**, and pressure are decreased and, eventually lost. Skin lesions of hypopigmented macules (flat and pale areas of the skin) also appear, as do nearly painless **ulcers** and increased dryness of the eyes. Eventually, large ulcerated areas are produced. Eventually facial disfiguration develops, along with loss of fingers and toes.

Although patients with leprosy are commonly thought not to suffer pain, neuroapthic pain caused by inflammation of peripheral nerve endings is increasingly recognized as a major complication of the disease in many patients. **Corticosteroids** may be given to reduce the inflammation.

The incubation period of the leprosy bacillus varies anywhere from six months to ten years. On an average, it takes four years for the symptoms of tuberculoid leprosy to develop. Probably because of the slow growth of the bacillus, lepromatous leprosy develops even more slowly, taking an average of eight years for the initial lesions to appear.

It is still not very clear how the leprosy bacillus is transmitted from person to person; about 50% of patients diagnosed with the disease have a history of close contact with an infected family member. Since untreated patients have a large number of *M. leprae* bacilli in their nasal secretions, it is thought that transmission may take place via nasal droplets. The milder tubercular form of leprosy may be transmitted by insect carriers or by contact with infected soil.

Some medical researchers contend that *M. leprae* is transmitted from one human to another through nasal secretions or droplets. However, other scientists think that the bacterium enters the body through breaks in the skin. As of 2014, the specific ways that the bacterium enters the body is being investigated by scientists.

The disease appears primarily in the poorest of the world's countries. In addition, environmental factors such as overpopulated areas, unhygienic living conditions, contaminated water, risk of other immune-compromising diseases, and insufficient diet/extreme **malnutrition** may also be contributing factors adding to the risk of leprosy.

Diagnosis

Leprosy is usually diagnosed through clinical investigations. One of the hallmarks of leprosy is the presence of AFB in smears taken from the skin lesions, nasal scrapings, or tissue secretions. In patients with LL leprosy, the bacilli are easily detected; however, in TT leprosy the bacteria are very few and almost impossible to find. In such cases, a diagnosis is made based on the clinical signs and symptoms, the type and distribution of skin lesions, and history of having lived in an endemic area. Generally, laboratory analysis is not used because such labs are rarely found in these very poor countries where leprosy is mostly found.

The signs and symptoms characteristic of leprosy can be easily identified by a health worker after a short training period. There is no need for a laboratory investigation to confirm a leprosy diagnosis, except in very rare circumstances.

In an endemic area, if smears from an individual show the presence of AFB, or if he/she has typical skin lesions, then that person should definitely be regarded as having leprosy. Usually, there is slight discoloration of the skin (sometimes called hypopigmented patches of skin) and loss of skin sensitivity along with redness of the area. Thickened nerves accompanied by weakness of muscles supplied by the affected nerve are very typical of the disease. One characteristic occurrence is a foot drop where the foot cannot be flexed upwards, affecting the ability to walk.

When laboratory tests are used, such tests usually include a CBC (**complete blood count**) test, liver function test, creatinine (clearance) test, and a nerve biopsy.

Treatment

A vaccine for leprosy is still not available. The most widely used drug for leprosy is dapsone (DDS). However, the emergence of dapsone-resistant strains prompted the introduction of multidrug therapy, or MDT. MDT combines dapsone, rifampin (Rifadin; also known as rifampicin), and clofazimine (Lamprene), all of which are powerful antibacterial drugs. Patients with MB leprosy are usually treated with all three drugs, while patients with PB leprosy are only given rifampin and dapsone. Usually three months after starting treatment, a patient ceases being infectious, though not everyone with this disease is necessarily infectious before treatment. Depending on the type of leprosy, the time required for treatment may vary from six months to two years or more.

Each of the drugs has minor side effects. Dapsone can cause nausea, **dizziness**, **palpitations**, **jaundice**,

WWW.BOOKBAZ.IR

and rash. A doctor should be contacted immediately if a rash develops. Dapsone also interacts with the second drug, rifampin. Rifampin increases the metabolizing of dapsone in the body, requiring an adjustment of the dapsone dosage. Rifampin may also cause **muscle cramps**, or nausea. If jaundice, flu-like symptoms or a rash appear, a doctor should be contacted immediately. The third drug, clofazimine may cause severe abdominal pain and **diarrhea**, as well as discoloration of the skin. Red to brownish black discoloration of the skin and bodily fluids, including sweat, may persist for months to years after use.

Thalidomide, the most famous agent of **birth defects** in the twentieth century, is now being used to treat complications of leprosy and similar diseases. Thalidomide regulates the immune response by suppressing a protein, **tumor necrosis factor** alpha.

Leprosy patients should be aware that treatment itself can cause a potentially serious immune system response called a lepra reaction. When **antibiotics** kill *M. leprae*, antigens (the proteins on the surface of the organism that initiate the body's immune system response) are released from the dying bacteria. In some people, when the antigens combine with the antibodies to *M. Leprae* in the bloodstream, a reaction called **erythema nodosum** leprosum may occur, resulting in new lesions and peripheral nerve damage. Cortisone-type medications and, increasingly, thalidomide are used to minimize the effects of lepra reactions.

Surgery may be performed in order to make cosmetic improvements to the patient. In some cases, severe ulcers caused by leprosy may be treated surgically with small skin grafts. In other cases, some movement of the limbs can be restored or, at least, some neural function improved.

Prognosis

Leprosy is curable; however, the deformities and nerve damage associated with leprosy are often irreversible. Prevention or **rehabilitation** of these defects is an integral part of management of the disease. **Reconstructive surgery**, aimed at preventing and correcting deformities, offers the greatest hope for disabled patients. Sometimes, the deformities are such that the patients will not benefit from this type of surgery.

Comprehensive care involves teaching patients to care for themselves. If the patients have significant nerve damage or are at high risk of developing deformities, they must be taught to take care of their insensitive limbs, similar to diabetics with lower leg nerve damage. Lacking the sensation of pain in many cases, the patients should constantly check themselves to identify cuts and **bruises**. If adequate care is not taken, these wounds become festering sores and a source of dangerous infection. Physiotherapy exercises are taught to the patients to maintain a range of movement in finger joints and prevent the deformities from worsening. Prefabricated standardized splints are available and are extremely effective in correcting and preventing certain common deformities in leprosy. Special kinds of footwear have been designed for patients with insensitive feet in order to prevent or minimize the progression of foot ulcers.

The genome of *M. leprae* has been sequenced since 2014. The completion of this project has allowed much more research to be performed in the search for better treatments and a cure for leprosy. Scientists are currently working on how the bacterium infects humans, how the infection is transmitted within the body, what the period of incubation is for the disease, and many more avenues toward solving the problem.

KEY TERMS

Endemic area—A geographical area where a particular disease is prevalent.

Gangrene—Death of tissue due to loss of blood supply followed by bacterial invasion and putrefaction.

Incubation period—The time it takes for symptoms to develop after initial exposure to a disease-causing organism.

Lesion—Any visible, local abnormality of the tissues of the skin, such as a wound, sore, rash, or boil.

Mucous membranes—The inner tissue that covers or lines body cavities or canals open to the outside, such as nose and mouth. These membranes secrete mucus and absorb water and salts.

Nasal scraping—Pathological material obtained for clinical study by scratching the inner surface of the nose with a clinical instrument.

Nodules—A small mass of tissue in the form of a protuberance or a knot that is solid and can be detected by touch.

Pathogen—Any disease-producing agent or microorganism.

Smear—A specimen prepared for microscopic study by spreading the material across a slide and treating it with a specific stain.

Prevention

By early diagnosis and appropriate treatment of infected individuals, even a disease as ancient as leprosy can be controlled. People who are in immediate contact with the leprosy patient should be tested for leprosy. Annual examinations should also be conducted on these people for a period of five years following their last contact with an infectious patient. Some physicians have advocated dapsone treatment for people in close household contact with leprosy patients.

The WHO Action Program for the Elimination of Leprosy adopted a resolution calling for the elimination of leprosy around the world by the year 2005. This goal was not reached, however; a computer simulation performed for WHO by a team of Dutch researchers in 2004 indicates that leprosy is likely to persist in some parts of the world until 2020, although its incidence will continue to decline.

The WHO Action Program has now defined a strategy to eventually eliminate the disease as a **public health** problem. Members of the program hope to reach a rate of 1 or less leprosy case per 10,000 population. As of 2014, this "elimination" rate of 1 per 10,000 have been reached in most countries with the highest rates of leprosy. In 2007, the countries of Mozambique and the Democratic Republic of the Congo reached this elimination rate. Other nations of the world are nearing this elimination rate but still have areas of high concentration within their boundaries. Some of these countries include Angola, Brazil, Central African Republic, India, Madagascar, Nepal, and Tanzania.

Leptospirosis

Definition

Leptospirosis is a febrile (**fever**) disease caused primarily by infection with the bacterium *Leptospira interrogans*, but also by other bacteria within the genus *Leptospira*. *L. interrogans* is sometimes classified as a spirochete because it has a spiral shape. It can be transmitted to humans by various wild animals such as rats, opossums, raccoons, foxes, and skunks. Domesticated animals such as dogs and livestock can also carry and transmit the disease. Humans may also acquire the disease through soil or water infected by such animals. This rare disease and contagious infection can range from very mild and symptomless to a more serious, even life-threatening form, that may be associated with kidney (renal) failure. German physician Adolf Weil (1848–1916) first described the disease in 1886. It was later observed in 1907 from a slice of renal tissue during a post mortem procedure.

Demographics

The disease is relatively rare in humans. Leptospirosis is usually found in tropical and subtropical areas,

WWW.BOOKBAZ.IR

especially around stagnant or slow-moving waters, but can be present anywhere worldwide. It is also more likely to be a problem during the months of July through October and February through March. The infection is often transmitted to humans after they have drunk water contaminated with animal urine. It can also be contracted through such contamination of breaks in the skin and through mucous membranes such as the eyes.

Leptospirosis is rarely found in the continental part of the United States. However, when it is present in the United States, it is most often located in the state of Hawaii. According to the Centers for Disease Control and Prevention (CDC), between 100 and 200 cases of leptospirosis are reported in the United States each year. In addition, nearly 75% of cases of leptospirosis in North America occur in males. Further, about 50% of cases happen in Hawaii, followed by the southern Atlantic, Gulf, and Pacific coastal states. However, because of the nonspecific symptoms of leptospirosis, it is believed that the occurrence in the United States is actually much higher. Leptospirosis occurs year-round in North America, but about half of the cases take place between July and October.

Description

An infection by the bacterium *Leptospira interrogans* goes by different names in different regions. Alternate names for leptospirosis include mud fever, canefield fever, Rat Catcher's Yellows, seven–day fever, swamp fever, cane cutter's fever, rice field fever, Stuttgart disease, Swineherd's disease, and Fort Bragg fever. More severe cases of leptospirosis are called Weil's syndrome or icterohemorrhagic fever.

Leptospirosis is called a **zoonosis** because it is a disease of animals that can be transmitted to humans. It can be a very serious problem in the livestock industry. *Leptospira* bacteria have been found in dogs, rats, livestock, mice, voles, rabbits, hedgehogs, skunks, possums, frogs, fish, snakes, and certain birds and insects. Infected animals pass the bacteria in their urine for months, or even years. In the United States, rats and dogs are more commonly linked with human leptospirosis than other animals.

Humans are considered accidental hosts and become infected with *Leptospira interrogans* by coming into contact with urine from infected animals. Transmission of the organism occurs through direct contact with urine, or through contact with soil, water, or plants that have been contaminated by animal urine. *Leptospira interrogans* can survive for as long as six months outdoors under favorable conditions. Leptospira bacteria can enter the body through cuts or other skin damage or through mucous membranes (such as the inside of the mouth and nose). Researchers believe that the bacteria may be able to pass through intact skin, although evidence for this hypothesis has not been obtained.

Once past the skin barrier, bacteria enter the blood stream and rapidly spread throughout the body. The infection causes damage to the inner lining of blood vessels. The liver, kidneys, heart, lungs, central nervous system, and eyes may be affected.

There are two stages in the disease process. The first stage is during the active Leptospira infection and is called the bacteremic or septicemic phase. The bacteremic phase lasts from three to seven days and presents as typical flu-like symptoms. During this phase, bacteria can be found in the patient's blood and cerebrospinal fluid. The second stage, or immune phase, takes place either immediately after the bacteremic stage or after a one to three day symptom-free period. The immune phase can last up to one month. During the immune phase, symptoms are milder but **meningitis** (inflammation of spinal cord and brain tissues) is common. Bacteria can be isolated only from the urine during this second phase.

Causes and symptoms

Leptospirosis is caused primarily by an infection with the bacterium *Leptospira interrogans*. Bacteria are spread through contact with urine from infected animals. Persons at an increased risk for leptospirosis include farmers, ranchers, slaughterhouse workers, miners, animal health care workers and veterinarians, fish farmers and processors, sewage and canal workers, cane harvesters, and soldiers. High-risk activities include care of pets (especially dogs); the raising of livestock; hunting and trapping; trail biking; freshwater swimming, rafting, canoeing, and kayaking; and participating in sports within muddy fields.

Symptoms of *Leptospira* infection appear within two to 26 days following exposure to the bacteria, with 10 days being the average number of days. Because the symptoms can be nonspecific, most people who have antibodies to *Leptospira* do not remember having had an illness. Eighty five to 90% of the cases are not serious and clear up on their own. Symptoms of the first stage of leptospirosis last three to seven days and include:

- fever (with a temperature of 100–105°F [38–41°C])
- severe headache
- muscle pain

- stomach pain
- chills
- nausea
- vomiting
- diarrhea
- back pain
- joint pain
- neck stiffness
- extreme exhaustion

Dry **cough**, **sore throat**, and body rash sometimes also occur. Other symptoms, which are usually less frequently observed, are enlarged lymph glands, liver, and spleen, abnormal sounds from the lungs, skin rash, and muscle tenderness or rigidity.

Following the first stage of disease, a brief symptom-free period ensues for most patients. The symptoms of the second stage vary in each patient. Most patients have a low-grade fever, **headache**, **vomiting**, and rash. Aseptic meningitis is common in the second stage, symptoms of which include headache and **photosensitivity** (sensitivity of the eye to light). *Leptospira* can affect the eyes and make them cloudy and yellow to orange colored. Vision may be blurred.

Ten percent of the persons infected with *Leptospira* develop a serious disease called Weil's syndrome. The symptoms of Weil's syndrome are more severe than those described above and there is no distinction between the first and second stages of disease. The hallmark of Weil's syndrome is liver, kidney, and blood vessel disease. The signs of severe disease are apparent after three to seven days of illness. In addition to those listed above, symptoms of Weil's syndrome include **jaundice** (yellow skin and eyes), decreased or no urine output, **hypotension** (low blood pressure), rash, anemia (decreased number of red blood cells), **shock**, and severe mental status changes. Red spots on the skin, "blood shot" eyes, and bloody sputum signal that blood vessel damage and hemorrhage have occurred.

Diagnosis

Leptospirosis can be diagnosed and treated by doctors who specialize in infectious diseases. During the bacteremic phase of the disease, the symptoms are relatively nonspecific. This often causes an initial misdiagnosis because many diseases have similar symptoms to leptospirosis. The later symptoms of jaundice and kidney failure together with the bacteremic phase symptoms suggest leptospirosis. Blood samples will be tested to look for antibodies to *Leptospira interrogans*. Blood samples taken over a period of a few days would show an increase in the number of antibodies. Isolating *Leptospira* bacteria from blood, cerebrospinal fluid (performed by spinal tap), and urine samples is diagnostic of leptospirosis. Tests for **white blood cell count** and creatine kinase may also be performed. It may take six weeks for *Leptospira* to grow in laboratory media. Most insurance companies cover the diagnosis and treatment of this infection.

Several diagnostic tests for leptospirosis have been devised that are more accurate as well as faster than standard cultures. One test uses flow cytometry light scatter analysis; this method can evaluate a sample of infected serum in as little as 90 minutes. A second technique is an IgM-enzyme-linked immunosorbent assay (ELISA), which detects the presence of IgM antibodies to *L. interrogans* in blood serum samples.

Treatment

Leptospirosis is treated with **antibiotics** (such as tetracycline or chloramphenicol), penicillin (Bicillin, Wycillin), doxycycline (Monodox, Vibramycin), or erythromycin (E-mycin, Ery-Tab). However, many doctors prefer to treat patients with ceftriaxone, which is easier to use than intravenous penicillin. Ciprofloxacin may be combined with other drugs in caring for patients who develop **uveitis**. It is generally agreed that antibiotic treatment during the first few days of illness is helpful. However, leptospirosis is often not diagnosed until the later stages of illness. The benefit of antibiotic treatment in the later stages of disease, however, is controversial. A rare complication of antibiotic therapy for leptospirosis is the occurrence of the Jarisch–Herxheimer reaction, which is characterized by fever, chills, headache, and muscle **pain**.

Patients with severe illness require hospitalization for treatment and monitoring. Medication or other treatment for pain, fever, vomiting, fluid loss, bleeding, mental changes, and low blood pressure may be provided. Patients with kidney failure require hemodialysis to remove waste products from the blood.

Prognosis

The majority of patients infected with *Leptospira interrogans* experience a complete recovery when treated promptly. Ten percent of patients develop eye inflammation (uveitis) up to one year after the illness. Other complications include excessive bleeding, meningitis, and Jarisch-Herxheimer reaction. In the United States, about one out of every 100 patients die from leptospirosis. Death is usually caused by

KEY TERMS

Hemodialysis—The removal of waste products from the blood stream in patients with kidney failure. Blood is removed from a vein, passed through a dialysis machine, and then put back into a vein.

Jarisch–Herxheimer reaction—A rare reaction to the dead bacteria in the blood stream following antibiotic treatment.

Meningitis—Inflammation of tissues in the brain and spinal cord. Aseptic meningitis refers to meningitis with no bacteria present in the cerebral spinal fluid.

Spirochete—Any of a family of spiral- or coil-shaped bacteria known as Spirochetae. *L. interrogans* is a spirochete, as well as are the organisms that cause syphilis and relapsing fever.

Zoonosis (plural, zoonoses)—Any disease of animals that can be transmitted to humans. Leptospirosis is an example of a zoonosis.

kidney failure, but has also been caused by **myocarditis** (inflammation of heart tissue), **septic shock** (reduced blood flow to the organs because of the bacterial infection), organ failure, and/or poorly functioning lungs. Mortality is highest in patients over 60 years of age.

Prevention

Persons who are at an extremely high risk (such as soldiers training in wetlands) can be pretreated with 200 milligrams (mg) of doxycycline once a week. As of 2014, no vaccine is available to prevent leptospirosis in humans, although similar vaccines have been formulated by veterinarians for dogs, swine, cattle, and other animals.

There are many ways to decrease the chances of being infected by *Leptospira*. These include:

- Avoid swimming or wading in freshwater ponds and slowly moving streams, especially those located near farms.
- Do not conduct canoe or kayak capsizing drills in freshwater ponds. Use a swimming pool instead.
- Boil or chemically treat pond or stream water before drinking it or cooking with it.
- Control rats and mice around the home.
- Have pets and farm animals vaccinated against *Leptospira*.
- Wear protective clothing (gloves, boots, long pants, and long-sleeved shirts) when working with wet soil or plants.

Lesch-Nyhan syndrome

Definition

Lesch-Nyhan syndrome, which is also known as HPRT deficiency or Kelley-Seegmiller syndrome, is a rare genetic disorder that affects males. Males with this syndrome develop physical handicaps, intellectual disabilities (ID), and kidney problems. It is caused by a total absence of a key enzyme that affects the level of

uric acid in the body. Self-injury or self-mutilation is a distinctive feature of this genetic disease.

Description

Lesch-Nyhan syndrome was first described in 1964 by Drs. Michael Lesch and William Nyhan. The enzyme deficiency that causes the disorder was discovered in 1967 by a researcher named Seegmiller. The syndrome is caused by a severe change (mutation) in a gene that encodes an enzyme known as hypoxanthine-guanine phosphoribosyl transferase, or HPRT. This gene was identified and sequenced by Friedmann and colleagues in 1985. HPRT catalyzes a reaction that is necessary to prevent the buildup of uric acid, a nitrogenous waste product that is ordinarily excreted from the body through the kidneys. A severe mutation in the HPRT gene leads to an absence of HPRT enzyme activity which, in turn, leads to markedly elevated uric acid levels in the blood (hyperuricemia). This buildup of uric acid is toxic to the body and is related to the symptoms associated with the disease. Absence of the HPRT enzyme activity is also thought to alter the chemistry of certain parts of the brain, such as the basal ganglia, affecting neurotransmitters (chemicals used for communication between nerve cells), acids, and other chemicals. This change in the nervous system is also related to the symptoms associated with Lesch-Nyhan syndrome.

Males with Lesch-Nyhan syndrome develop neurologic problems during infancy. Infants with Lesch-Nyhan syndrome have weak muscle tone (hypotonia) and are unable to develop normally. Affected males develop uncontrollable writhing movements (athetosis) and muscle stiffness (spasticity) over time. Lack of speech is also a common feature of Lesch-Nyhan syndrome. The most dramatic symptom of Lesch-Nyhan syndrome, however, is the compulsive self-injury seen in 85% of affected males. This self-injury involves the biting of their own lips, tongue, and finger tips, as well as head banging. This behavior leads to serious injury and scarring.

Lesch-Nyhan syndrome affects approximately one in 380,000 live births. It occurs evenly among races. Almost always, only male children are affected, although a few cases of the disorder in girls have been reported. Women carriers usually do not have any symptoms. Women carriers can occasionally develop inflammation of the joints (**gout**) as they get older.

Causes and symptoms

Severe changes (mutations) in the HPRT gene completely halt the activity of the enzyme HPRT. There have been many different severe mutations identified in the HPRT gene. These mutations may be different between families. The HPRT gene is located on the X chromosome. Since the HPRT gene is located on the X chromosome, Lesch-Nyhan syndrome is considered X-linked. This means that it only affects males.

A person's sex is determined by their chromosomes. Males have one X chromosome and one Y chromosome. Females, on the other hand, have two X chromosomes. Males who possess a severe mutation in their HPRT gene will develop Lesch-Nyhan syndrome. Females who possess a severe mutation in their HPRT gene will not. They are considered to be carriers. This is because females have another X chromosome without the mutation that prevents them from getting this disease. If a woman is a carrier, she has a 50% risk with any **pregnancy** to pass on her X chromosome with the mutation. Therefore, with every male pregnancy she has a 50% risk to have an affected son, and with every female pregnancy she has a 50% risk to have a daughter who is a carrier.

At birth, males with Lesch-Nyhan syndrome appear completely normal. Development is usually normal for the first few months. Symptoms develop between three to six months of age. Sand-like crystals of uric acid in the diapers may be one of the first symptoms of the disease. The baby may be unusually irritable. Typically, the first sign of nervous system impairment is the inability to lift their head or sit up at an appropriate age. Many patients with Lesch-Nyhan will never learn to walk. By the end of the first year, writhing motions (athetosis), and spasmodic movements of the limbs and facial muscles (chorea) are clear evidence of defective motor development.

The compulsive self-injury associated with Lesch-Nyhan syndrome begins, on average, at three years. The self-injury begins with biting of the lips and tongue. As the disease progresses, affected individuals frequently develop finger biting and head banging. The self-injury can increase during times of **stress**.

Males with Lesch-Nyhan disease may also develop kidney damage due to **kidney stones**. Swollen and tender joints (gout) is another common problem.

Diagnosis

The diagnosis of Lesch-Nyhan syndrome is based initially on the distinctive pattern of the child's symptoms, most commonly involuntary muscle movements or failure to crawl and walk at the usual ages. In some cases the first symptom is related to overproduction of uric acid; the parents notice "orange sand" in the child's diapers. The "sand" is actually crystals of uric acid tinged with blood.

WWW.BOOKBAZ.IR

KEY TERMS

Amniocentesis—A procedure performed at 16–18 weeks of pregnancy in which a needle is inserted through a woman's abdomen into her uterus to draw out a small sample of the amniotic fluid from around the baby. Either the fluid itself or cells from the fluid can be used for a variety of tests to obtain information about genetic disorders and other medical conditions in the fetus.

Athetosis—A condition marked by slow, writhing, involuntary muscle movements.

Basal ganglia—A section of the brain responsible for smooth muscular movement.

Chorea—Involuntary, rapid, jerky movements.

Chorionic villus sampling (CVS)—A procedure used for prenatal diagnosis at 10–12 weeks gestation. Under ultrasound guidance a needle is inserted either through the mother's vagina or abdominal wall and a sample of cells is collected from around the early embryo. These cells are then tested for chromosome abnormalities or other genetic diseases.

Enzyme—A protein that catalyzes a biochemical reaction or change without changing its own structure or function.

Mutation—A permanent change in the genetic material that may alter a trait or characteristic of an individual, or manifest as disease, and can be transmitted to offspring.

Neurotransmitter—Chemical in the brain that transmits information from one nerve cell to another.

Palsy—Uncontrolable tremors.

Spasticity—Increased mucle tone, or stiffness, which leads to uncontrolled, awkward movements.

Measuring the amount of uric acid in a person's blood or urine can not definitively diagnose Lesch-Nyhan syndrome. It is diagnosed by measuring the activity of the HPRT enzyme through a blood test. When the activity of the enzyme is very low it is diagnostic of Lesch-Nyhan syndrome. It can also be diagnosed by DNA testing. This is also a blood test. DNA testing checks for changes (mutations) in the HPRT gene. Results from DNA testing are helpful in confirming the diagnosis and also when the child's family is interested in prenatal testing for future pregnancies.

Prenatal diagnosis is possible by DNA testing of fetal tissue drawn by **amniocentesis** or **chorionic villus sampling** (CVS). Fetuses should be tested if the mother is a carrier of a change (mutation) in her HPRT gene. A woman is at risk of being a carrier if she has a son with Lesch-Nyhan syndrome or someone in her family has Lesch-Nyhan syndrome. Any woman at risk of being a carrier should have DNA testing through a blood test.

Treatment

There are no known treatments for the neurological defects of Lesch-Nyhan. Allopurinol (Aloprim, Zyloprim), a drug usually prescribed to lower the risk of gout attacks, can lower blood uric acid levels. This medication is a preventive; it does not correct many of the symptoms of Lesch-Nyhan. Other drugs that are given to manage spasticity include baclofen (Lioresal), which is a muscle relaxant, and benzodiazepine tranquilizers.

Some patients with Lesch-Nyhan syndrome have their teeth removed to prevent self-injury. Restraints may be recommended to reduce self-destructive behaviors, although some patients can be managed with a combination of behavioral modification therapy and medications.

Prognosis

With strong supportive care, infants born with Lesch-Nyhan can live into adulthood with symptoms continuing throughout life. Few live beyond 40, however, with death usually resulting either from kidney failure or from aspiration **pneumonia**. Sudden unexpected death from **respiratory failure** is common in these patients.

At present, there are no preventive measures for Lesch-Nyhan syndrome. However, recent studies have indicated that this genetic disorder may be a good candidate for treatment with gene replacement therapy. Unfortunately, the technology necessary to implement this therapy has not yet been perfected.

Leukemia stains

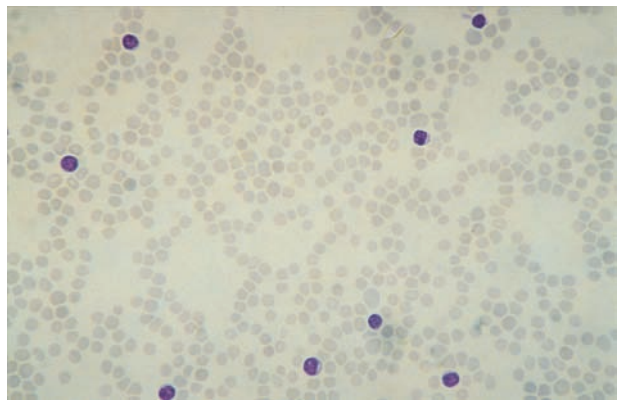
Definition

Leukemia stains are laboratory tests done on bone marrow or blood samples to help diagnose specific types of leukemia.

Purpose

Leukemia stains are done to diagnose and classify leukemia. Blood contains red cells, several varieties of white cells, and platelets. Cancerous overproduction of any one type of cell produces one of many types of leukemia. A patient's specific type of leukemia must be classified in order to provide the best treatment and most accurate prognosis.

The type and maturity of the cells involved are identified by analyzing blood and bone marrow under a microscope. Often, however, the abnormality or immaturity of the cells make it difficult to identify the cell types with certainty. Special leukemia stains help to distinguish one cell type from another.



A magnified stain of chronic lymphocytic leukemia cells. *(Custom Medical Stock Photo, Inc.)*

Description

Special stains are added to bone marrow or blood that has been smeared on a microscope slide. Cell types react differently to the chemicals in the stains.

If the patient has few white cells, a buffy coat smear is made. A tube of blood is spun in a centrifuge. Red cells fall, plasma rises, and white cells settle in a thin middle layer called the buffy coat. The smear is made from this layer.

Sudan black B stain

This stain distinguishes between acute lymphoblastic leukemia (cells stain positive) and acute myeloblastic leukemia (cells stain negative).

Periodic acid-Schiff stain (PAS)

The PAS stain is primarily used to identify erythroleukemia, a leukemia of immature red blood cells. These cells stain a bright fuchsia.

Terminal deoxynucleotidyl transferase stain (TdT)

The TdT stain differentiates between acute lymphoblastic leukemia (cells stain positive) and acute myelogenous leukemia (cells stain negative).

Leukocyte alkaline phosphatase (LAP)

The LAP stain is used to determine if an increase of cells is due to chronic myelogenous leukemia or a noncancerous reaction to an infection or similar conditions. Cells from a noncancerous reaction stain positive with many intense blue granules; cells from chronic myelogenous leukemia have few blue granules.

WWW.BOOKBAZ.IR

Tartrate-resistant acid phosphatase stain (TRAP)

The TRAP stain is primarily used to identify **hairy cell leukemia** cells. These cells stain with purple to dark red granules.

Myeloperoxidase stain

The myeloperoxidase stain distinguishes between the immature cells in acute myeloblastic leukemia (cells stain positive) and those in acute lymphoblastic leukemia (cells stain negative).

Leukocyte specific esterase

This stain identifies granulocytes, which show red granules.

Leukocyte nonspecific esterase

Nonspecific esterase stain identifies monocytes and immature platelets (megakaryocytes), which show positive black granules.

Preparation

Leukemia stains are done on smears of blood or bone marrow. To collect blood, a healthcare worker draws blood from a vein in the inner elbow region. Collection of the sample takes only a few minutes.

When bone marrow is needed, the person is given local **anesthesia**. Then the physician inserts a needle through the skin and into the bone—usually the breast bone or hip bone—and 0.5–2 mL of bone marrow is withdrawn. This procedure takes approximately 30 minutes.

Aftercare

Patients sometimes feel discomfort or bruising at the puncture site after blood collection. They may also become dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Collection of bone marrow is done under a physician's supervision. The patient is asked to rest after the procedure and is watched for weakness and signs of bleeding.

Results

A normal blood or bone marrow smear shows no evidence of leukemic cells. The expected reaction of cells varies with the type of stain.

KEY TERMS

Bone marrow—The spongy tissue inside large bones where blood cells are formed.

Buffy coat—The thin layer of concentrated white blood cells that forms when a tube of blood is spun in a centrifuge.

Leukemia—Any of several cancers of the bone marrow characterized by the abnormal increase of a type of blood cell.

Leukemia stains—Special stains added to smears of blood or bone marrow, performed to diagnose and classify leukemia.

Leukemia stain results that help diagnosis and classify leukemia are supported by the results of other laboratory tests and the person's clinical condition.

Leukemias, acute

Definition

Acute leukemia is a type of cancer in which excessive numbers of abnormal white blood cells are produced in blood-forming tissue such as the bone marrow and released into the bloodstream. It arises from malignant transformation of white cells known as B-lymphocytes or T-lymphocytes, occurring at the stem cell level.

Description

Acute leukemia progresses rapidly, whereas chronic leukemia progresses more slowly, often over a period of years. Acute leukemia is classified by the type of white blood cell that undergoes malignant transformation. The most common of the acute leukemias are the following:

- Acute lymphoblastic leukemia (ALL) or acute lymphocytic leukemia, in which excessive numbers of lymphoblasts, or immature lymphocytes, are produced.

- Acute myeloblastic leukemia (AML), also known as acute myeloid leukemia and acute nonlymphocytic leukemia (ANLL), in which excessive numbers of immature myeloid cells are produced.

All leukemias are cancers of specific white blood cells produced in the lymphatic system, mainly in the bone marrow. Bone marrow is the spongy tissue found inside the large bones of the body. Besides the bone marrow, the lymphatic system includes the lymphatic vessels (tiny tubes that branch like blood vessels into all parts of the body) and lymph nodes (pea-shaped organs that are found along the network of lymphatic vessels), which both carry lymph, a milky fluid containing specialized white cells that normally fight disease. Organs of the lymphatic system include the spleen in the upper abdomen, the thymus gland beneath the breastbone, and the tonsils in the throat. In leukemia, the malignant cells circulate throughout the lymphatic system and in the blood and may infiltrate various organs, especially the liver, spleen, lymph nodes, central nervous system, kidneys, testicles, and ovaries.

The cells found in the blood include: red blood cells (RBCs) that carry oxygen and other materials such as iron to all tissues of the body; white blood cells (WBCs) that are a critical part of the immune system designed to fight infection; and platelets that play an important role in blood coagulation. White blood cells are subdivided further into three main types: granulocytes (polymorphonuclear cells known as polys), monocytes, and lymphocytes.

The granulocytes, as their name suggests, contain particles (granules). These granules contain special proteins (enzymes) and several other substances that can break down chemicals and destroy microorganisms, including bacteria and viruses. Monocytes are also important in defending the body against invading pathogens. ANLL involves the monocytes and/or granulocytes.

Lymphocytes are of two primary types: T-lymphocytes and B-lymphocytes, each with different functions in the immune system. B cells protect the body by making antibodies against foreign substances or against antigens on the surface of cells. Antibodies are proteins that can attach to the surfaces of bacteria and viruses. This attachment signals other cell types to seek out and destroy the antibody-coated organisms. T cells protect the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the infected cell. T cells recognize these proteins and make certain chemicals that are capable of destroying the virus-infected cells. In addition, T cells can destroy some types of cancer cells. Either T-lymphocytes or B-lymphocytes are involved in ALL, but in general, B-cell leukemias are more common.

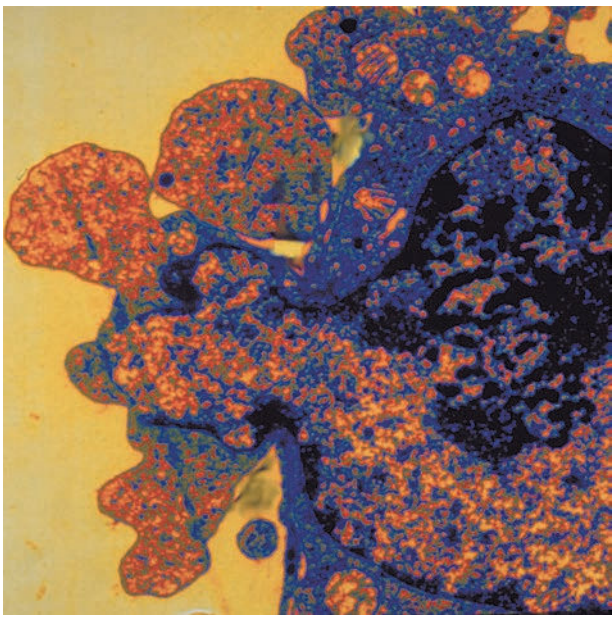
Bone marrow makes stem cells, which are the precursors or early forms of the different blood cells. These stem cells mature through stages into RBCs, WBCs, or platelets. In acute leukemias, the maturation process of the white blood cells is interrupted. The immature cells (or blasts), transformed mainly by either genetic or viral sources, proliferate rapidly and begin to accumulate in various organs and tissues, thereby affecting their normal function. This uncontrolled proliferation of the immature cells in the bone marrow affects the production of the normal red blood cells and platelets as well. Essentially, in leukemia, the abnormal proliferation of the specific types of white cells and their reduced cell death (apotosis) leads to the replacement of normal cells by the malignant cells.

Risk factors

Several risk factors have been identified as playing a role in the development of acute leukemia, including the following:

- exposure to ionizing radiation such as post-atomic bomb radiation

WWW.BOOKBAZ.IR



An enhanced transmission electron microscopy (TEM) image of acute myelogenous leukemia cells. *(Custom Medical Stock Photo, Inc.)*

- exposure to medical radiation such as that used to treat cancer patients
- previous treatment with anticancer drugs (procarbazine, cyclophosphamide, melphalan, and etoposide or teniposide)
- previous infection with viruses such as human T-lymphotrophic virus and Epstein-Barr virus (present in mononucleosis)
- history of immunodeficiency disorders (HIV, AIDS), chronic myeloproliferative disorders, and disorders due to chromosomal translocations such as Down syndrome, Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, and infantile X-linked agammaglobulinemia
- history of cigarette smoking
- exposure to certain toxic chemicals such as benzene
- use of the antibiotic chloramphenicol

Having a history of diseases that damage the bone marrow, such as **aplastic anemia**, or a history of cancers of the lymphatic system also increases the risk for developing acute leukemias.

Demographics

Leukemias account for 2% of all cancers. The incidence of acute leukemia is slightly higher among men than women. Although leukemia is the most common form of childhood cancer and accounts for one-third of all cancers in children, many more adults than children are diagnosed with leukemia. Half of the cases of adult leukemia occur in people aged 60 or older. Chronic leukemia is diagnosed slightly more often than acute leukemia in adults. The American Cancer Society (ACS) estimates that approximately 52,380 new cases of all types of leukemia are likely to be diagnosed in 2014 in the United States and 24,000 people were likely to die from the disease.

In adults, the most common type of leukemia is AML, which has several subtypes involving different cells (myeloid, myeloid-monocytic, monocytes, erythroid and megakaryocytic). In children, two-thirds of leukemia cases are acute lymphocytic leukemia (ALL), which is most prevalent in early childhood, with a peak incidence between the ages of two and four years. ALL represents about 26% of childhood cancers in children and 8% of cancers diagnosed in adolescents. Chronic leukemia is rare in children.

New cases of ALL diagnosed in 2014 were estimated to reach 6,020, affecting 2,670 children younger than age 14 and 410 adolescents aged 15–19. It was estimated that 1,440 children and adolescents were likely to die of the disease in 2014.

ALL is more common among Caucasians than among African Americans, whereas acute myeloid leukemia (AML) affects both races equally. Acute promyelocytic leukemia (APL) is a subtype of AML that occurs in younger adults (average age 30) and particularly those of Hispanic descent. People with Jewish ancestry have a higher likelihood of developing leukemia.

Causes and symptoms

The precise cause of most leukemias is not known, but several explanations for the malignant transformation of cells have been suggested. The human T-cell leukemia virus (HTLV-I), a virus with similarities to the human **immunodeficiency** virus (HIV), is believed to be the causative agent for a rare form of ALL. The number of treatment-related cases of AML (individuals previously treated for cancer with **chemotherapy** and/or **radiation therapy**) is increasing, particularly among survivors of childhood and adolescent cancers such as Hodgkin disease, lymphoma, sarcoma, **testicular cancer**, and **breast cancer**.

Genetic causes are also suggested, primarily changes in the location (translocation) of chromosomes in the nuclei of cells. For example, leukemic cells may have a normal number of chromosomes, but they may be abnormal in their forms. The

Philadelphia (Ph) chromosome may be present, which is considered to be an unfavorable sign in ALL.

Individuals with leukemia often have anemia, infection, easy bruising, and bleeding (e.g., petechiae, or tiny red spots under the skin, nosebleeds, bleeding gums, and menstrual irregularity), which may appear only days or weeks before diagnosis. Other symptoms of leukemia are more vague and nonspecific. A patient may experience all or some of the following symptoms:

- weakness or chronic fatigue
- fever of unknown origin, chills and flu-like symptoms
- weight loss that is not due to dieting or exercise
- frequent bacterial or viral infections
- headaches
- skin rash
- nonspecific bone pain
- blood in urine or stools
- swollen and tender lymph nodes
- abdominal fullness
- night sweats
- more rarely, sores in the eyes or on the skin

The proliferation of cells may result in an enlarged spleen or liver, and these organs may be felt in the upper abdomen. In rare cases, the central nervous system is affected and the patient has headaches, **vomiting**, irritability, and possibly seizures.

Diagnosis

Examination

No screening tests are available for early detection of leukemias. If the doctor suspects leukemia, a thorough **physical examination** is done to look for enlarged lymph nodes in the neck, underarm area, and pelvic region, as well as swollen gums, enlarged liver or spleen, **bruises**, or pinpoint red **rashes** all over the body. A careful personal and family history of previous illnesses and treatments received is also taken.

Tests

A **complete blood count** with differential is usually the first test done, and it determines the numbers of red and white cells in the blood, and differential analysis of a blood smear identifies the percentages of different white cell types, mature and immature (blasts). The presence of a large percentage of blast cells may strongly suggest leukemia; however, the diagnosis must be confirmed by more specific tests and possibly gene studies. Urine tests will be ordered to check for microscopic amounts of blood in the urine.

Standard imaging studies, including chest x ray, **computed tomography scans** (CT scans), and **magnetic resonance imaging** (MRI), may be performed to check whether the leukemic cells have invaded other areas of the body such as the bones, chest, kidneys, abdominal organs, or brain.

Sophisticated cytogenetic studies may be performed to examine the number and shape of chromosomes in the DNA of individual blast (immature) cells. Immunophenotyping of cells in the bone marrow is done to identify specific cell types that may be associated with leukemia. This procedure involves removing a sample of bone marrow and applying various stains that help a pathologist identify some of the proteins attached to the surface of the cells.

Procedures

A bone marrow biopsy may be taken by aspiration or needle to confirm the diagnosis of leukemia. During the biopsy, a cylindrical piece of bone and marrow is removed from a large bone such as the hipbone or chest bone (sterum). These samples are sent to the pathology laboratory where they are examined under a microscope by a hematologist, oncologist, or pathologist. Finding between 25– 95% blast cells in bone marrow confirms leukemia. Cytogenetics, immunophenotyping, and molecular biology determine whether the blasts represent ALL or AML. In addition to the diagnostic biopsy, another biopsy usually is performed during the treatment phase of the disease to see if the leukemia is responding to therapy.

A spinal tap (**lumbar puncture**) is another procedure that the doctor may order to diagnose leukemia. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw a sample of cerebrospinal fluid that will be examined microscopically to look for leukemic cells.

Treatment

For a successful outcome, treatment for acute leukemia must begin as soon as possible. The goal of treatment is to arrest the leukemic disease process and induce remission. Leukemia treatment has two phases. The first phase is called induction therapy. As the name suggests, the primary aim of this phase of treatment is to reduce the number of leukemic cells and induce remission in the patient. Once the patient shows no obvious signs of leukemia (i.e., no leukemic cells are detected in blood tests and bone marrow biopsies), the patient is said to be in remission. The second phase of treatment is consolidation or

WWW.BOOKBAZ.IR

maintenance therapy, and the goal is to kill any remaining cancer cells and to maintain the remission for as long as possible.

Chemotherapy is the primary treatment for leukemias. Sometimes **stem cell transplantation** is also performed. Surgery is not considered an option for treating leukemias since bone marrow is the source of the abnormal cells, and spreading is the result of malignant cells circulating in the body via the bloodstream and the lymphatic system.

Chemotherapy

Chemotherapy is the use of specific **anticancer drugs** to kill cancer cells. It is usually the treatment of choice in leukemia and is used to relieve symptoms and achieve long-term remission. Generally, combination chemotherapy, in which multiple drugs are used simultaneously, is more efficient than using any single drug alone. Some drugs may be administered intravenously through a vein in the arm, whereas others may be given by mouth in the form of pills. If the cancer cells have invaded the brain, then chemotherapeutic drugs may be put into the fluid that surrounds the brain through a needle in the brain or back (intrathecal chemotherapy).

Targeted therapies such as immunologic or biologic therapies, including the use of **monoclonal antibodies**, are increasingly being used to treat acute leukemia by killing specific types of malignant cells without killing normal cells. For example, the monoclonal antibody rituximab (Rituxan) may be used to treat adult ALL patients whose leukemic cells are positive for the CD20 antigen. Patients with Philadelphia-chromosome positive ALL and patients with AML may receive potent tyrosine kinase inhibitors such as imatinib (Gleevec), dasatinib (Sprycel), or nilotinib to treat their leukemia. Many more such targeted therapies were in development as of 2014.

Radiation

Radiation therapy, which involves the use of x rays or other high-energy rays to kill cancer cells and shrink tumors, may be used in some cases. For acute leukemias, external (outside the body) radiation therapy is usually applied. If the leukemic cells have spread to the brain or other organs, radiation therapy may be directed to the involved organ system.

Prognosis

As with most cancers, the prognosis for leukemia depends on the patient's age, general health status, and response to therapy. Prognosis is fairly good for children and younger adults with ALL and poorer among infants and elderly patients or those with liver or kidney diseases and a WBC count more than 25,000. Among children, more than 95% achieve remission and normal blood counts are restored, and in adults, 70–90% achieve remission. The five-year survival rate is 75% in children and 60%–88% will remain in remission after five years, depending upon the cell type. Among adults, 30–40% have disease-free survival for five years.

AML has only a slightly poorer prognosis than ALL, with remission induced in 50–85% of patients. About 20% to 40% of patients have long-term disease-free survival, which can increase to as much as 50% in younger patients who have received intensive chemotherapy or stem cell transplantation. Patients with certain cytogenetic profiles have more favorable responses to therapy and improved survival. If specific chromosomes are missing or karyotypes are abnormal, the risk of relapse is higher and prognosis can be markedly poorer.

Prevention

Many cancers can be prevented by changes in lifestyle or diet, which reduce the risk factors. However, in leukemias, the main risk factors, such as chromosomal translocations and previous immunodeficiency or genetic disorders, are not modifiable, which makes prevention impossible. Avoiding exposure to tobacco smoke and toxic chemicals may help to reduce risk in some individuals. People who are at an increased risk for developing leukemia due to various types of exposure and preexisting conditions are advised to undergo periodic medical checkups and blood tests.

Leukemias, chronic

Definition

Chronic leukemia is a type of cancer in which excessive numbers of abnormal white blood cells are produced in blood-forming tissue such as the bone marrow and released into the bloodstream. It usually begins slowly and progresses over a period of years, or it can have a long chronic phase that eventually changes into an accelerated phase with complications similar to those of acute leukemia. Chronic leukemia arises from the malignant transformation of specific white cells at the stem cell level.

Description

Chronic leukemias are named for the type of white blood cell that undergoes malignant transformation. In chronic lymphocytic leukemia (CLL), mature-appearing abnormal white blood cells called lymphocytes, usually B-lymphocytes (only 2–3% of cases involve T-cells), are produced. In chronic myelogenous leukemia (CML), also known as chronic granulocytic leukemia (CGL), uncontrolled proliferation of white blood cells called granulocytes occurs. Although blasts, the hallmark of acute leukemia, are also present in chronic leukemia, it is primarily the T- or B-lymphocytes that undergo malignant transformation. Chronic leukemias typically progress slowly with less rapid growth than acute leukemia, which progresses rapidly. However, CML has an accelerated phase that more closely resembles acute leukemia.

All leukemias are cancers of specific white blood cells produced in the lymphatic system, mainly in the bone marrow. Bone marrow is the spongy tissue found inside the large bones of the body. Besides the bone marrow, the lymphatic system includes the lymphatic vessels (tiny tubes that branch like blood vessels into all parts of the body) and lymph nodes (pea-shaped organs that are found along the network of lymphatic vessels), which both carry lymph, a milky fluid containing specialized white cells that normally fight disease. Organs of the lymphatic system include the spleen in the upper abdomen, the thymus gland beneath the breastbone, and the tonsils in the throat. In leukemia, the malignant cells circulate throughout the lymphatic system and in the blood and may infiltrate various organs, especially the liver, spleen, lymph nodes, central nervous system, kidneys, testicles, and ovaries.

The cells found in the blood include red blood cells (RBCs) that carry oxygen and other materials such as iron to all tissues of the body, white blood cells (WBCs) that are a critical part of the immune system designed to fight infection, and platelets that play an important role in blood coagulation. White blood cells are subdivided further into three main types: granulocytes (polymorphonuclear cells known as polys), monocytes, and lymphocytes.

The granulocytes, as their name suggests, contain particles (granules). These granules contain special proteins (enzymes) and several other substances that can break down chemicals and destroy microorganisms, including bacteria and viruses.

Lymphocytes are of two primary types, T-lymphocytes and B-lymphocytes, each with different functions in the immune system. B-cells protect the body by making antibodies against foreign substances or against antigens on the surface of cells. Antibodies are proteins that can attach to the surfaces of bacteria and viruses. This attachment signals other cell types to seek out and destroy the antibody-coated organisms. T-cells protect the body against viruses. When a virus enters a cell, it produces certain proteins that are projected onto the surface of the infected cell. T-cells recognize these proteins and make certain chemicals that are capable of destroying the virus-infected cells. In addition, T-cells can destroy some types of cancer cells.

Bone marrow makes stem cells, which are the precursors or early forms of the different blood cells. These stem cells mature through stages into RBCs, WBCs, or platelets. In CLL, the specific B-cells undergo malignant transformation in the bone marrow, which spreads to the lymph nodes and organs of the lymph system, finally resulting in an enlarged spleen and liver and reductions in the number of RBCs (anemia), WBCs (**neutropenia**), and platelets (**thrombocytopenia**). In CML, it is the translocation known as Philadelphia chromosome that leads to excessive production of granulocytes, primarily in the bone marrow, but also in the spleen and liver.

WWW.BOOKBAZ.IR

Other cells such as RBCs, monocytes, and even T-cells and B-cells are involved in the process. Normal stem cells, however, are retained and can reemerge after the CML has been arrested.

Risk factors

Several established risk factors are related to the development of leukemias, including exposure to certain chemicals such as benzene and having hereditary gene mutations or chromosome translocations, especially the Philadelphia chromosome. Exposure to Agent Orange, a herbicide used in the Vietnam War, and long-term exposure to pesticides is reported to increase the risk of developing leukemia. A family history of leukemia also appears to be a risk factor. First-degree relatives (parents, siblings, and children) of CLL patients are two to four times more likely to be diagnosed with CLL as people who have no family history of CLL. Exposure to high-dose radiation, such as radiation from an atomic blast or from a nuclear reactor accident increases the risk of leukemia. A higher incidence of leukemia has also been observed among people with **immunodeficiency** disorders such as HIV, chronic myeloproliferative disorders, and disorders due to chromosomal translocations such as **Down syndrome**, Fanconi anemia, Bloom syndrome, ataxia-telangiectasia, and infantile **X-linked agammaglobulinemia**.

Having a history of diseases that damage the bone marrow, such as **aplastic anemia**, or a history of cancers of the lymphatic system puts people at a high risk for developing leukemias. Similarly, the use of anticancer medications, immunosuppressants, and the antibiotic chloramphenicol are also considered risk factors for developing leukemias.

Demographics

Leukemias account for about 2% of all cancers and occur in both sexes and in all ages. The incidence of leukemia is slightly higher among men than women. Although leukemia is the most common form of childhood cancer and accounts for one-third of all cancers in children, many more adults are actually diagnosed with leukemia. Half of the cases of adult leukemia occur in people who are aged 60 or older. Chronic leukemia is diagnosed slightly more often than acute leukemia in adults and only rarely occurs in children. The American Cancer Society (ACS) estimates that approximately 52,380 new cases of leukemia of all kinds were likely to be diagnosed in 2014 in the United States and 24,000 people were likely to die from the disease.

Chronic leukemias are named for the specific type of white blood cells (WBC) involved. CLL, which involves lymphocytes, is by far the most common chronic type. CML, also called chronic granulocytic leukemia, chronic myelogneous leukemia, and chronic myeloid leukemia, involves myeloid cells called granulocytes. Lymphoid leukemias are significantly more common among Caucasians than among African Americans, whereas myeloid leukemias are only slightly more common in Caucasians.

The incidence of CLL increases with age. About 80% of cases of CLL are observed in patients who are age 60 or older, with an average age at diagnosis of 72 years. Rarely is CLL diagnosed in a patient who is younger than age 40, and it almost never occurs in children or adolescents. The American Cancer Society estimated that approximately 15,720 new cases of CLL were likely to be diagnosed in 2014 and 4,600 Americans were likely to die from the disease. Average lifetime risk of developing CLL is about 1 in 200. CLL affects both men and women. Among patients younger than 65, CLL is slightly more common in men but occurs equally between men and women among patients older than age 75. The incidence of CLL has increased significantly since the 1960s. However, many scientists attribute this increase to more reliable diagnosis than to the disease being more common than in the past. Fifty years ago, only one of ten CLL patients was diagnosed during the early phase. In early 2014, half of all CLL patients were diagnosed in the early phase of the disease.

CML accounts for about 15% of all adult leukemias. The average lifetime risk of developing CML is about 1 in 588. Although CML can occur at any age, the average age at diagnosis is 64 years. It is rarely diagnosed before age 10. The American Cancer Society estimated about 5,980 new cases of CML were likely to be diagnosed in the United States in 2014 and about 810 people were likely to die from the disease.

Causes and symptoms

Causes

As of 2014, the precise cause of most leukemias was not known, but several explanations for the malignant transformation of cells had been proposed. In about 95% of patients with CLL, specific CD+ B-lymphocytes undergo malignant transformation in the bone marrow, which spreads to the lymph nodes and other components of the lymph system. This may be triggered by genetic causes or other causes associated with risk. Genetic causes primarily involve changes in

the location (translocation) of chromosomes in the nuclei of cells. Although leukemic cells may have a normal number of chromosomes, they may be abnormal in their forms. About 95% of patients with CML have the Philadelphia chromosome (Ph). Ph chromosome develops when a piece of chromosome 9 that contains the cancer gene (oncogene) c-abl translocates to chromosome 22 and fuses to the gene BCR. This forms BCR-ABL, which is important in the origination of CML.

Symptoms

The symptoms of chronic leukemia are generally vague and non-specific and are frequently overlooked until they are noticed on routine **physical examination**, especially when a routine blood test such as a **complete blood count** (CBC) is performed. A CBC may show unusually large numbers of certain white cells, primarily lymphocytes and monocytes, in the blood. Chronic leukemias may go for years without manifesting any symptoms at all but can also develop symptoms similar to **acute leukemias**. Chronic myeloid leukemia, in particular, has a two- or three-stage progression: a chronic phase that can last for several years; an accelerated phase; and a terminal blastic phase, a malignant phase in which immature granulocytes are suddenly generated in huge numbers, producing symptoms similar to those of acute leukemia. In such cases, a patient may experience all or some of the following symptoms:

- weakness or chronic fatigue
- fever of unknown origin, chills, and flu-like symptoms
- unexplained weight loss
- frequent bacterial or viral infections
- viscous (sticky) blood (which slows down the supply to various organs)
- headache
- non-specific bone pain
- easy bruising
- bleeding from gums or nose
- blood in urine or stools
- swollen and tender lymph nodes and/or spleen
- abdominal fullness
- night sweats
- petechiae, or tiny red spots under the skin
- priapism, or persistent, painful erection of the penis
- rarely, sores in the eyes or on the skin

Diagnosis

Examination

If leukemia is suspected based on symptoms or results of a blood count done for other reasons, a thorough physical examination is conducted to look for enlarged lymph nodes in the neck, underarm area, and pelvic region. Swollen gums and an enlarged liver or spleen are other signs of chronic leukemia that may be present on physical examination. A personal and family history of previous illnesses and treatments is also taken.

Tests

A complete blood count with differential is usually the first test done, and it determines the numbers of red and white cells in the blood and differential analysis of a blood smear identifies the percentages of different white cell types, mature and immature (blasts). The presence of a large percentage of blast cells may strongly suggest leukemia; however, the diagnosis must be confirmed by more specific tests and possibly gene studies. Urine tests are ordered to check for microscopic amounts of blood in the urine.

Standard imaging studies, including chest x ray, **computed tomography scans** (CT scans), and **magnetic resonance imaging** (MRI), may be performed to check whether the leukemic cells have invaded other areas of the body such as the bones, chest, kidneys, abdominal organs, or brain.

Sophisticated cytogenetic studies may be performed to examine the number and shape of chromosomes in the DNA of individual blast (immature) cells. The presence of the Philadelphia (Ph) chromosome is a crucial factor in the diagnosis of CML. Immunophenotyping of cells in the bone marrow is done to identify specific cell types that may be associated with leukemia. This procedure involves removing a sample of bone marrow and applying various stains that help a pathologist identify some of the proteins attached to the surface of the cells.

Procedures

A bone marrow biopsy may be taken by aspiration or needle to confirm the diagnosis of leukemia. During the biopsy, a cylindrical piece of bone and marrow is removed from a large bone such as the hipbone or chest bone (sterum). These samples are sent to the pathology laboratory where they are examined under a microscope by a hematologist, oncologist, or pathologist. In addition to the diagnostic biopsy, another biopsy is usually performed during

WWW.BOOKBAZ.IR

the treatment phase of the disease to see if the leukemia is responding to therapy.

A spinal tap (**lumbar puncture**) is another procedure that the doctor may order to diagnose leukemia. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw a sample of cerebrospinal fluid, which will be examined microscopically to look for leukemic cells.

Laboratory findings indicate whether a CML patient is in the chronic phase of the disease or has entered the accelerated phase. In the chronic phase, fewer than 10% of cells in the blood or marrow are blasts or immature cells. Once there are more than 10% but less than 20% of blasts detected in the blood or bone marrow, the patient is said to be in the accelerated phase of CML. When greater than 20% of blasts are detected in the blood or the bone marrow, the CML patient is said to be in the blast phase. Other names for this phase are the acute phase or blast crisis, behaving like a more aggressive acute form of leukemia.

Some CLL patients have a condition called hypogammaglobulinemia, which can be identified in certain blood tests. Immunoglobulins are important parts of the immune system that rids the body of infection. Patients with hypogammaglobulinemia have very low levels of immunoglobulins (IgG, IgA and others) and are less able to fight infection.

Standard imaging tests such as chest x rays, computed tomography (CT) scans, and magnetic resonance imaging (MRI) may be used to determine whether malignant cells have invaded other areas of the body, such as the bones, chest, kidneys, abdomen, or brain.

Procedures

A bone marrow biopsy may be performed, during which a small piece of bone and marrow is removed, generally taken from the hip bone. A spinal tap (lumbar puncture) may also be done if central nervous system involvement is suspected. In this procedure, a small needle is inserted into the spinal cavity in the lower back to withdraw some cerebrospinal fluid and to look for leukemic cells.

Treatment

Treatment of CLL

Because the long-term prognosis for many patients with CLL is excellent, many patients (about one-third) receive no treatment at all at first. Many patients (about one-third) go for years before developing aggressive disease that requires treatment. Another one-third of patients require immediate treatment intervention at the time of diagnosis.

Treatment for CLL is typically initiated in a stepwise progression from the least invasive method of monitoring blood work and symptoms at regular intervals, known as watchful waiting, to treatment with **chemotherapy**, monoclonal antibody therapy, **corticosteroids** (for associated anemia and thrombocytopenia), and/or **stem cell transplantation**. Decisions to initiate treatment are based on the stage of disease, presence of symptoms, and disease activity.

Treatment for early stage CLL is started only when one of the following conditions appears:

- Symptoms of the disease are growing worse, including a greater degree of fever, weight loss, night sweats, and so forth.
- The spleen is enlarging or enlargement of the spleen has become painful.
- Disease of the lymph nodes has become severe.
- The condition of the bone marrow has deteriorated, and a marked reduction in the number of blood platelets and anemia are present.
- The population of malignant lymphocytes is growing rapidly.
- The patient is developing numerous bacterial infections due to reduced immunoglobulins.

Therapy for CLL usually starts with chemotherapy. Depending on the stage of the disease, single or multiple drugs may be given. Drugs commonly prescribed include fludarabine, cladribine, chlorambucil, and cyclophosphamide, or combinations of these drugs. The monoclonal antibody rituximab and/or cyclophosphamide have been used successfully for CML with response rates up to 75%. Another monoclonal antibody, alemtuzumab, has had a 75–80% response rate in patients not treated previously. Alemtuzumab may be used when patients are refractory to fludarabine-based regimens. Close monitoring for life-threatening infections is important with the use of alemtuzumab. It is being combined effectively with chemotherapy to completely clear bone marrow infiltration of malignant cells.

Another option for CLL patients is allogenic stem cell transplantation. This option is typically reserved for patients younger than 65 years old because of the intensity of the conditioning regimen and due to the high risk of mortality.

In 2014 clinical trials were ongoing to evaluate the effectiveness of newer agents to treat CLL, including flavopiridol and lenalidomide.

Treatment of CML

In the early 2000s, targeted therapy using tyrosine kinase inhibitors (TKi) had become the treatment of choice for CML. This is because the fusion gene BCR-ABL, which is associated with the Philadelphia chromosome translocation, is involved in the production of a specific tyrosine kinase. These drugs seem to work best for patients in the chronic phase of the disease, although they may also be effective for patients with more advanced disease. TKi drugs, including imatinib mesylate (Gleevec), which was the first approved TKi, and the subsequent dasatinib and nilotinib, have shown positive responses without relapse among newly diagnosed patients with Philadelphia chromosome or BCR-ABL positive chronic phase CML. Side effects of these drugs may include **diarrhea**, nausea, **fatigue**, muscle **pain**, and skin **rashes**, as well as swelling around the eyes, feet, or abdomen. Differences in the toxicity profile of the different TKi drugs and the health status of patients determine the choice of a specific TKi agent.

Chemotherapy use in CML is reserved for patients as part of treatment preceding stem cell transplantation. **Radiation therapy** is used only sparingly in the treatment of CML. It may be used to shrink an enlarged spleen, to treat pain caused by an increase in malignant cells in the bone marrow, or in low doses as pretreatment for stem cell transplantation.

Because of the demonstrated long-term effectiveness of targeted TKi drugs in sustaining remission in most CML patients, the role of stem cell transplantation was being reevaluated in 2014. The effectiveness of targeted TKi agents in treating both chronic and acute leukemias spurred ongoing research to develop new drugs of this type with improved toxicity profiles, fewer side effects, and better patient outcomes.

The typical treatment protocol for CML by phase includes the following: chronic phase—treatment with TKi; accelerated phase—may include TKi, which has induced remission although it may not be long-term and chemotherapy may be used to induce remission prior to undergoing stem cell transplantation; blast phase—high dose TKi may be effective for patients who have not been treated previously. The TKi drugs dasatinib and nilotinib may be more effective in this phase, but that is determined case by case. Patients who do not respond to a TKi drug may be considered for stem cell transplantation, which is more likely to be effective if remission of CML can be induced prior to transplantation. Treatment for CML is not known to be curative except after successful stem cell transplantation.

Prognosis

For many CLL patients, the prognosis is based on stage at diagnosis. Using the Binet and Rai staging systems criteria, patients staged as low risk usually survive more than ten years. Patients staged as intermediate risk usually survive about seven years. Patients staged as high risk usually survive about two to five years. The average patient survives nine or more years after diagnosis.

CML prognosis has improved with the consistent use of TKi agents. With imatinib, more than 90% of patients survive five years after diagnosis of the chronic phase. Prior to the use of imatinib, the first TKi approved for CML, 5–10% of patients died within two years of diagnosis, and another 10–15% died each successive year. Most deaths from CML occur after a blast phase or accelerated phase. Oh chromosome-negative CML and chronic myelomonomcytic leukemia have a poorer prognosis than Ph Chromosome-positive CML.

Prevention

There is no known way to prevent chronic leukemia. People who are at an increased risk for developing chronic leukemia because of proven exposure to radiation, Agent Orange or long-term exposure to pesticides, and people with a family history of chronic leukemia, are advised to undergo periodic medical evaluations with accompanying blood tests.

NSAID—Non-steroidal anti-inflammatory drug such as ibuprofen.

Leukocytosis

Definition

Leukocytosis is a condition characterized by an elevated number of white cells in the blood.

Description

Leukocytosis is a condition that affects all types of white blood cells. Other illnesses, such as neutrophilia, lymphocytosis, and granulocytosis, target specific types of white blood cells. Normal white blood cell counts are 4,300–10,800 white blood cells per microliter. Leukocyte or white blood cell levels are considered elevated when they are between 15,000–20,000 per microliter. The increased number of leukocytes can occur abnormally as a result of an infection, cancer, or drug intake; however, leukocytosis can occur normally after eating a large meal or experiencing **stress**.

Causes and symptoms

Leukemias can cause white blood cell counts to increase to as much as 100,000. Each kind of white cell can produce a leukemia. Apart from leukemias, nearly all leukocytosis is due to one type of white blood cell, the polymorphonuclear leukocyte (PMN). These conditions are more accurately referred to as neutrophilia.

The most common and important cause of neutrophilia is infection, and most infections cause neutrophilia. The degree of elevation often indicates the severity of the infection. Tissue damage from other causes raises the white count for similar reasons. **Burns**, infarction (cutting off the blood supply to a region of the body so that it dies), crush injuries, inflammatory diseases, poisonings, and severe diseases, like kidney failure and **diabetic ketoacidosis**, all cause neutrophilia.

Counts almost as high occur in leukemoid (leukemia-like) reactions caused by infection and non-infectious inflammation.

Drugs can also cause leukocytosis. Cortisone-like drugs (prednisone), lithium, and NSAIDs are the most common offenders.

Non-specific stresses also cause white blood cells to increase in the blood. Extensive testing of medical students reveals that neutrophilia accompanies every examination. Vigorous **exercise** and intense excitement also cause elevated white blood cell counts.

Diagnosis

A **complete blood count** (CBC) is one of the first tests obtained in any medical setting. More than 11,000 white cells in a cubic millimeter of blood is considered high. Bone marrow biopsy may help clarify the cause.

Treatment

Relieving the underlying cause returns the count to normal.

Prognosis

By treating the underlying condition, white blood cell counts usually return to normal

Leukotriene inhibitors

Definition

Leukotriene inhibitors are prescription medications that treat **asthma** and some **allergies** by blocking the formation or activity of leukotrienes—small mediator chemicals produced by cells in the body.

Purpose

More than 50 million Americans suffer from asthma and allergies. Asthma is one of the most prevalent chronic diseases in the United States, affecting 9 million (12.7%) of children. Seasonal allergies affect 20–40 million (20%) of Americans, about 40% of them children. It is estimated that 60–70% of those with asthma also suffer from **allergic rhinitis**, allergies affecting the mucous membranes of the nose.

Asthma, an inflammation of the bronchial airways, and seasonal allergies and allergic **rhinitis** involve several chemical mediators including histamine and leukotrienes. Leukotrienes are a class of unsaturated fatty-acid chains containing 20 carbon atoms.

During an asthma attack or within minutes of exposure to an allergen such as dust or pollen, leukotrienes are released by a type of blood cell in the lungs, causing the following responses:

- contraction of the bronchial airway muscles
- inflammation of the airway linings
- swelling and narrowing of the airways
- production of mucus and fluid
- wheezing and shortness of breath
- nasal congestion

Leukotriene inhibitors may decrease the symptoms of mild to moderate allergen-induced asthma, improve nighttime symptoms, and reduce the number of acute asthma attacks. Taken daily on a long-term basis they may help to prevent or control the symptoms of persistent asthma—asthma with symptoms that last at least two days per week or two nights per month. They also are prescribed for children with frequent or more severe asthma attacks and for those who dislike or have difficulty using asthma inhalers. Although leukotriene inhibitors may decrease the need for inhaled beta-agonists or **corticosteroids**, they are not used to treat asthma attacks. Leukotriene inhibitors also may be used to treat symptoms of allergic rhinitis or short-term seasonal allergies, including sneezing, runny nose, **itching**, and **wheezing**.

Description

Leukotriene inhibitors are often called leukotriene:

- blockers
- modifiers
- antagonists
- pathway modifiers

When they were first introduced in 1996, leukotriene inhibitors represented the first new class of asthma medication in two decades. Classified as anti-inflammatories, they were originally developed to improve lung function in asthmatics by relaxing the smooth muscles around the bronchial airways and by reducing lung inflammation.

Types of leukotriene inhibitors

The available leukotriene inhibitors are: montelukast (Singulair), zafirlukast (Accolate), and zileuton (Zyflo).

Montelukast and zafirlukast are leukotriene-receptor antagonists that prevent leukotriene from binding to cell receptors and initiating the chain of events leading to symptoms of allergy and asthma. Montelukast works rapidly. It is the only leukotriene inhibitor that has been approved by the U.S. Food and Drug Administration (FDA) for use in children as young as two, as well as for the treatment of seasonal allergies.

Zafirlukast is a synthetic peptide that inhibits the receptor binding of three leukotreines (LTC4, LTD4, and LTE4) that cause smooth muscle constriction. It is used for mild to moderate persistent asthma, exercise-induced asthma, and the management of allergic rhinitis in those aged seven and older.

Zileuton is a 5-lipooxygenase pathway inhibitor that interferes with the synthesis of LTA4, LTC4, LTD4, and LTE4. It is used to treat chronic asthma in adolescents and adults.

Effectiveness

Leukotriene inhibitors may be prescribed along with **inhaled corticosteroids** for control of mild to moderate, persistent asthma. Used alone they are less effective than low-dose inhaled corticosteroids. However, they enable some people to reduce their doses of inhaled corticosteroids. Leukotriene inhibitors may be an option for people with mild asthma who want to avoid corticosteroids, which can cause serious side effects with long-term use. When used in conjunction with beta-agonists, leukotriene inhibitors reduce symptoms and may lower the beta-agonist usage.

WWW.BOOKBAZ.IR

Leukotriene inhibitors appear to decrease the symptoms of seasonal allergic rhinitis. Although they may relieve nasal congestion better than **antihistamines**, they are less effective than corticosteroid nasal sprays. A leukotriene inhibitor combined with an antihistamine may be more effective than either drug alone.

Leukotriene inhibitors have helped some children who suffer from nocturnal asthma, exercise- and aspirin-induced asthma, allergic rhinitis, and seasonal allergies.

Clinical studies

Montelukast appears to be an effective asthma controller in about one-third of patients. Another one-third receives no benefit. However, most long-term studies have found that standard inhaled corticosteroids are more effective for controlling asthma than either beta-agonists or leukotriene inhibitors.

A 2003 analysis of 13 clinical studies found that Singulair and Accolate resulted in 60% more asthma flare-ups and other symptoms as compared with traditional asthma treatments. Patients using inhaled corticosteroids had fewer daytime symptoms and night awakenings than those taking Singulair or Accolate. The researchers advised against switching to a leukotriene inhibiter unless the dosage of inhaled medication is less than 400 micrograms per day.

A 2005 study sponsored by Merck, the maker of Singulair, found that a one-year course of Singulair was useful for treating two- to five-year-olds with occasional asthma attacks that were triggered by respiratory infections. Singulair reduced this type of asthma flare-up by 32% as compared with a control group receiving a placebo. Singulair also delayed the onset of the first asthma flare-up and reduced the need for inhaled medication. However, it did not reduce the length or severity of the flare-up once it had begun. The researchers suggested that children with infection-triggered asthma should begin taking a leukotriene inhibitor before the start of the flu season or at the onset of an upper-respiratory-tract infection.

Another 2005 study found that children whose asthma improved with montelukast alone were younger and had had asthma for a shorter period of time as compared with children whose asthma improved only with inhaled corticosteroids. Among the children whose lung function improved by at least 7.5%, 5% took montelukast alone, 23% were on inhaled corticosteroids only, and 17% were on both medications.

Other uses

Leukotriene inhibitors have been used successfully to treat inflammations of the esophagus (esophagitis) or stomach and intestines (**gastroenteritis**) that are caused by white blood cells called eosinophils that are involved in allergic reactions. Montelukast has been used to successfully treat symptoms of interstitial **cystitis**, a chronic inflammation of the bladder.

Recommended dosage

Montelukast is taken once per day in the evening so as to relieve morning allergy symptoms. Although dosing may vary, average daily doses of montelukast for asthma and seasonal allergies are: children aged 1–5: one 4-mg chewable tablet or 4-mg oral granules (one packet), swallowed whole or mixed in a spoonful of soft food; children aged 6–14: one 5-mg chewable tablet; children over 14 and adults: one 10-mg tablet.

The average doses of zafirlukast for children aged 7–11 are 10-mg tablets twice a day. Children aged 12 and older and adults usually take 20-mg tablets twice a day. Zafirlukast is taken one hour before or two hours after a meal, since food reduces its bioavailability by about 49%.

The average dose of zileuton is a 600-mg tablet four times per day for children aged 12 and older and adults.

Leukotriene inhibitors are expensive. Missed doses should be taken as soon as possible unless it is almost time for the next dose, in which case the dose should be skipped.

Precautions

Although leukotriene inhibitors are considered safe, they can raise the levels of liver enzymes. The FDA recommends **liver function tests** monthly for the first three months on medication, followed by quarterly monitoring for the next year, and continued interim testing. Zileuton is contraindicated for those with elevated liver enzymes, active **alcoholism**, or **liver disease**. Increased levels of liver enzymes may be detectable in the blood within two months of starting zileuton. Zileuton can affect liver function and, one rare occasions, can damage the liver.

It is unclear whether leukotriene inhibitors should be taken during **pregnancy**. Zafirlukast and zileuton should not be used by a woman who is **breastfeeding**. Both medications have been found to increase the risk of mild to moderate respiratory tract infections in patients aged 55 and older.

Medical conditions that may interfere with the use of montelukast include: allergies to **aspirin** or non-steroidal anti-inflammatories (NSAIDs); liver disease, which can increase the blood levels of the drug; and **phenylketonuria** because chewable tablets may contain aspartame.

A healthcare provider should be contacted if an increased number of short-acting bronchodilator inhalations are needed to relieve an acute asthma attack or if more than the maximum number of daily inhalations are required while using zileuton.

To be effective montelukast and zafirlukast must be taken at the same time every day. Zileuton must be taken at regularly spaced intervals every day, even if asthma symptoms appear to improve. Montelukast should be continued through an acute asthma attack in addition to rescue medication.

Side effects

Although leukotriene inhibitors generally have few side effects and those may subside as the body adjusts to the drug, headaches are common with these medications. Headaches occur in 18–19% of those taking montelukast and in 25% of those taking zileutin. Among 7 to 11 year olds on zanfirlukast, 4.5% suffer from headaches, as do 12.9% of those aged 12 and over.

Other less common side effects of leukotriene inhibitors include:

- rash
- fatigue
- dizziness
- abdominal pain
- nausea and vomiting
- diarrhea

Montelukast appears to cause fewer side effects than other leukotriene inhibitors and is less likely to affect the liver. Side effects occurring in less than 4.2% of patients include:

- heartburn
- weakness
- fever
- nasal congestion
- cough
- dental pain
- rarely, pus in the urine

Rare side effects of zileuton include:

- itching
- flu-like symptoms
- upper right abdominal pain
- yellow eyes or skin (jaundice)

Interactions

Drugs that may interact with montelukast include:

- aspirin
- NSAIDs
- phenobarbital
- rifampin

Zafirlukast and zileuton can raise the blood levels of the asthma medication theophylline (Theo Dur and others) and the blood thinner warfarin (Coumarin). Theophylline levels and blood-clotting times should be monitored frequently.

Medications that may interact with zafirlukast include:

- aspirin
- blood pressure medications
- some seizure medications

KEY TERMS

Allergic rhinitis—Nasal symptoms caused by an allergic reaction.

Asthma—A disease that causes the bronchial airways to narrow, swell, and produce mucus, making breathing difficult.

Beta-agonist—Beta2-agonist; beta-adrenergic agonist; a bronchodilator medication—inhaled or oral—that relaxes the muscles surrounding the airways to relieve asthma symptoms.

Corticosteroids—Inhaled medications for long-term control of asthma.

Leukotrienes—A class of small molecules produced by cells in response to allergen exposure; they contribute to allergy and asthma symptoms.

Montelukast (Singulair)—An inhibitor that prevents leukotrienes from binding to cell receptors; taken over time, montelukast can reduce or prevent symptoms of asthma and allergies.

Zafirlukast (Accolate)—An inhibitor that prevents leukotrienes from binding to cell receptors; taken over time, zafirlukast can help reduce or prevent asthma symptoms.

Zileuton (Zyflo)—A medication that interferes with the biosynthetic pathway that produces leukotrienes; used to help prevent asthma attacks.

LGBT health

Definition

LGBT (lesbian, gay, bisexual, and transgender) individuals are as diverse as the general population in terms of race, ethnicity, age, religion, education, income, and family history. A number of health concerns are unique to or shared by the LGBT community, however, including an increased risk of certain cancers, infectious and sexually transmitted diseases (STDs), and mental health disorders, issues relating to **nutrition** and weight, tobacco use, and substance abuse, and discrimination by health care and insurance providers.

Description

The definitions of different sexual identities have shifted over the years, as have the perceptions and stereotypes of the general population. Because of the wide range of behaviors and identities that exist in the LGBT community, it is difficult to develop an inclusive definition. It is generally accepted, however, that gay men and lesbians are sexually attracted to or participate in sexual behaviors with individuals of the same gender, while bisexual men and women are sexually attracted to or participate in sexual behaviors with individuals of both genders. Transgender individuals live part or full-time in a gender role opposite to their genetic sex.

Estimates suggest that approximately 2.8% of men and 1.4% of women identify as being gay, lesbian, or bisexual while 9.1% of men and 4.3% of women have participated in sexual behavior with someone of the same gender at least once. The true extent of the transgender community has not been well researched in the United States. Note that estimates of the LGBT community are based on self-reported information and actual rates may be higher.

Certain issues arise when trying to define sexual orientation. Many gay men and lesbians have participated in or continue to participate in sexual activities with members of the opposite sex but choose not to identify as heterosexuals or bisexuals. Others have never participated in sexual activities at all yet still identify as gay, lesbian, or bisexual. Some men and women identifying as bisexuals are in long-term, monogamous relationships with individuals of the same or opposite sex. Male-to-female (MTF) or female-to-male (FTM) transgender individuals may or may not identify themselves as gay or lesbian.

The implications of these identity issues are far-reaching. Misdiagnoses or improper medical recommendations might be made by health care providers

who have mistakenly assumed sexual behaviors or risks from the patient's stated identity. For example, a provider might incorrectly assume that a lesbian patient has never had sexual intercourse with a male and therefore would not have contracted STDs. It has been difficult to closely estimate the numbers of LGBT individuals in the United States because of varying definitions. Likewise, the statistics in medical or social studies and surveys on LGBT issues might vary widely depending on what definitions were provided for the respondents. Because of this, many researchers have opted for the more inclusive terms of "men who have sex with men" (MSM) and "women who have sex with women" (WSW) to categorize gay, lesbian, and bisexual respondents.

Important health care issues

Many LGBT individuals have difficulty revealing their sexual identity ("coming out") to their health care providers. They may fear discrimination from providers or believe that their confidentiality might be breached. In some cases health care workers have been poorly trained to address the needs of LGBT individuals, have difficulty communicating with their LGBT patient, or feel uncomfortable providing care for LGBT patients. In addition, many questions posed in questionnaires or examinations are heterosexually biased (e.g., asking a lesbian which birth control methods she uses).

Other reasons why LGBT individuals are often hesitant to share their sexual identity are more logistical. Many insurance companies deny benefits to long-term partners on the basis that they are not married. LGBT patients may have inadequate access to health care, either because they live in a remote rural area or in the crowded inner city. Some same-sex partners encounter discrimination in hospitals and clinics when they are denied the rights usually given to spouses of a patient such as visiting, making medical decisions, and participating in consultations with physicians.

Some of the health concerns and risk factors that are relevant to LGBT individuals may be shared by the general population, while others are more specific to the LGBT community, and still others are specific to different subgroups of LGBT individuals. These health concerns may be grouped into the following areas:

- Sexual behavior issues: STDs such as human immunodeficiency virus (HIV) and acquired immune deficiency syndrome (AIDS), hepatitis A virus (HAV), hepatitis B virus (HBV), bacterial vaginosis, gonorrhea, chlamydia, and genital warts (human papillomavirus or HPV); anal, ovarian, and cervical cancer.
- Cultural issues: body image, nutrition, weight, and eating disorders; drug and alcohol abuse; tobacco use; parenting and family planning.
- Discrimination issues: inadequate medical care; harassment at work, school, or home; difficulty in obtaining housing, insurance coverage, or child custody; violence.
- Sexual identity issues: conflicts with family, friends, and work mates; psychological issues such as anxiety, depression, and suicide; economic hardship.

CANCER. Cancer is the second leading cause of death (after **heart disease**) in the United States. In 2014, it was estimated that about 1.6 million individuals were diagnosed with cancer and about 585,600 lost their lives as a result. LGBT individuals are at an increased risk for certain types of cancers. In the United States, the National LGBT Cancer Network reports that there are approximately 1 million LGBT cancer survivors.

Several studies indicated that lesbians appear to have a higher risk for developing uterine, breast, cervical, endometrial, and ovarian cancers. This is partially related to higher rates of risk factors such as **obesity**, alcohol use, tobacco use, and nulliparity (not bearing children). Lesbians are less likely than heterosexual women to visit a doctor for routine Pap screening that can detect **cervical cancer**. Lesbians also have additional risk of developing **ovarian cancer**, due to inadequate access to health care, nulliparity, and not using **oral contraceptives** (use of oral contraceptives has been shown to decrease the risk of getting ovarian cancer).

Gay and bisexual men (or more generally, men who have sex with men [MSM]) are at higher risk of developing non-Hodgkin's lymphoma, Hodgkin's disease, and **anal cancer**. Kaposi's sarcoma, an AIDS-associated cancer, are also found in the gay community at rates higher than the general population. Anal cancer is associated with transmission of **human papillomavirus** (HPV), and the risk factors associated with MSM are also associated with increased rates of anal cancer (i.e., **smoking**, having many sexual partners, and receiving anal intercourse).

AIDS. The United States Centers for Disease Control and Prevention (CDC) estimates that the number of new cases of HIV is remaining stable, with approximately 50,000 new cases each year, but acknowledges that this figure is still high. Those bearing the greatest burden of **AIDS** are gay, bisexual and other men who have sex with men (MSM). The CDC reports that

WWW.BOOKBAZ.IR

MSM account for approximately 4% of the male population in the United States but in 2010, this group accounted for more than three-quarters of new HIV infections in men and nearly two-thirds of all new infections. The CDC estimated in 2011 more a cumulative estimate of diagnosed cases of AIDS of 1.1 million. In 2009, it was estimated that more than 1.1 million people ages 13 and up in the United States were living with HIV but not yet showing symptoms (HIV positive). More than 70% of HIV infections are transmitted through sexual contact. Traditionally in the United States, the majority of cases were found in homosexual or bisexual men. African Americans are at highest risk for severe effects from AIDS.

The six most common categories of transmitting the HIV virus are male-to-male sexual contact, use of injection drugs, both male-to-male sexual contact and injection of drugs, heterosexual contact and a category called "other".

Persons who have HIV/AIDS are at higher risk for developing cancer. About one-quarter of all deaths from AIDS are the result of non-HIV causes, and cancer accounts for a significant portion of these deaths. For example, anal and lung cancer occur more frequently in HIV patients than in those who do not have HIV.

FAMILY PLANNING. The American Fertility Association is a resource for family planning for the LGBT community, providing information on the legal and medical issues associated with LGBT parenting.

Options for lesbians who wish to become parents include intrauterine insemination, **in vitro fertilization**, and reciprocal in vitro fertilization. Sperm donors may be known males or unknown. An assisted reproduction attorney can provide legal advice.

Gay men who wish to build a family usually do so via surrogacy or egg donor.

Trangendered persons may be able to preserve fertility before they have sexual reassignment surgery.

Adoption may be an alternative for LGBT couples. Laws regarding adoption for LGBT parents vary for each state.

PSYCHIATRIC DISORDERS. In 1973, the American Psychiatric Association removed homosexuality from their list of mental disorders. Nevertheless, American society has been slow to fully accept of members of the LGBT community. As a result, members of this community often find themselves rejected by their families, socially stigmatized for their sexual orientation, treated unequally by laws and the justice system, and subject to physical and emotional abuse for their lifestyles. These pressures, plus the continuing **stress** caused by the need some LGBT individuals feel to conceal their sexual orientation from family, LGBT employers, and larger society lead to an increased occurrence of depressive illness, **anxiety disorders**, and drug and alcohol abuse.

KEY TERMS

Nulliparity—The condition of being nulliparous, or not bearing offspring.

NUTRITION AND BODY IMAGE. Diet and nutritional factors are associated with a number of diseases including cancer, **stroke**, diabetes, heart disease, and **osteoporosis**. It has been shown that lesbians are more likely than heterosexual women to be obese, have a higher **body mass index** (BMI), have a nutritionally poorer diet, and have higher rates of smoking and alcohol use, but they are also more likely to have a healthier **body image** than heterosexual women. Gay men and adolescents, on the other hand, have been shown to have increased rates of eating disorder behaviors than heterosexual men (e.g., **anorexia nervosa**, bulimia, and binge eating) and a poorer body image.

DRUG, ALCOHOL, AND TOBACCO USE. **Marijuana** and cocaine use has been shown to be higher among lesbians than heterosexual women. The incidence of the use of some drugs is higher in gay men than heterosexual men; these include marijuana, psychedelic drugs, ecstasy, **barbiturates**, and stimulants such as amyl or butyl nitrate ("poppers"). Although alcohol use has declined in the LGBT community since the 1990s, the rate is still higher among young LGBT individuals.

Cigarette smoking is responsible for 430,000 deaths a year in the United States, with an estimated 3,000 nonsmokers dying as a result of exposure to secondhand smoke. In 2004 the rate of smoking among all adults was 28%. In contrast, 50% of gay men, lesbians and bisexuals were noted to be smokers. Lesbians are more than two times as likely to become heavy smokers than heterosexual women.

Prevention

There are numerous ways that health care providers can improve the access to and experience of health care services for LGBT individuals. These include:

- rewording questionnaires and examinations to be inclusive of LGBT patients

- providing referrals to social service agencies and counseling services that are LGBT-friendly
- taking educational courses that are sensitive to the needs of LGBT patients
- treating the families of LGBT patients as one would the families of heterosexual patients
- maintaining the strictest code of confidentiality
- developing and maintaining health care centers or clinics that address LGBT-specific needs
- asking non-threatening questions to determine if a person is at risk of an STD
- educating patients of risk factors associated with STDs, possible vaccines, and treatments available
- providing services to individuals in the process of disclosing their sexual identity and, if applicable, their families

Lice infestation

Definition

Lice infestation is a condition in which large numbers of lice are present on a person's scalp, body, or pubic area. It is called an infestation rather than an infection because the parasites live on the skin and outside of the body rather than in the internal organs. Lice are tiny insects that can spread from one person to another through close contact; through sharing such personal items as clothing, hats, combs, or hairbrushes; or through lying on a bed, pillow, or carpet that has been in contact with someone with lice.

Demographics

The demographics of lice infestation vary depending on the type of lice involved. On the whole, lice infestations are common in the general population; there are at least 12 million cases in the United States each year, although this figure is only an estimate.

Head lice infestations are often not reported because people find them socially embarrassing—even though the Centers for Disease Control and Prevention (CDC) states that "Personal hygiene or cleanliness in the home or school has nothing to do with getting head lice." The number of all three types of lice infestations in Europe as well as North America has increased in recent years; a recent study of schoolchildren in Belgium, Turkey, and the Czech Republic found that rates of head lice infestations ranged from 9–16%.

Head lice are most common in schoolchildren between the ages of 3 and 11, and their families. Girls are more likely to be infested than boys because they are more likely to share clothing and other personal items with friends. It can be difficult to prevent a child from picking up head lice at school because of the amount of close contact among children and their belongings.

Body lice infest both children and adults; there is no difference in frequency between men and women. Homeless people and others who live in crowded conditions without opportunities to bathe or shower regularly are at greatest risk of getting body lice. Pubic lice are most common in people between the ages of 14 and 40 who are sexually active.

There is some seasonal difference in lice infestations in temperate climates; head lice infestations are more common during the warmer months while body and pubic lice infestations are more common in the fall and winter.

Description

Lice are a long-standing pest, having infested prehistoric humans as well as ancient humans after the invention of writing; the oldest known fossils of lice eggs are at least 10,000 years old. In modern societies, there are three related species of human lice that live on different parts of the body:

- head lice, *Pediculus humanus capitis*
- body lice, *Pediculosis humanus corporis*
- pubic lice, *Phthirus pubis,* commonly called "crab" lice

The three types of lice that infest humans are somewhat different in size and outward appearance. Head lice are 1–2 mm long, white or gray in color, and have flattened abdomens. The female louse lays her nits (eggs) close to the base of a hair shaft and attaches them to it with a sticky glue-like substance. The glue is what makes it so difficult to remove the nits from the hair shaft.

Body lice are about twice the size of head lice, between 2 and 4 mm long. The body louse lives in the seams of clothing, emerging at night to feed on the person's body. Pubic lice are smaller and broader, about 1.2 mm long. They have larger front claws, which is why pubic lice are sometimes called "crabs." The claws enable pubic lice to cling to the coarse hairs in the human groin and armpit areas.

Pediculosis capitis is an infestation of head lice. A body lice infestation is called pediculosis corporis. Pediculosis palpebrarum or Phthiriasis palpebrarum, caused by crab lice, is an infestation of the eyebrows and eyelashes.

Lice infestations are not usually dangerous. However, head lice infestations present a serious **public health** problem because they spread easily among schoolchildren. In general, lice infestations occur in crowded, unsanitary facilities including prison, military, and refugee camps. Lice infestations also occur frequently among the homeless.

Lice are transmitted through personal contact or infected clothing, bedding, or towels. Pubic lice are sexually transmitted. Lice do not jump, hop, or fly and they do not live on pets.

Risk factors

Risk factors for lice infestation include:

- Close body-to-body contact between family members or playmates.
- Sharing personal belongings, including headphones, combs, brushes, hats, scarves, and other personal items.
- Contact with contaminated furniture or bedding. Couch cushions and upholstery can harbor lice as well as pillows and sheets or blankets.
- Homelessness or imprisonment.
- Sexual contact with a large number of partners.

KEY TERMS

Crabs—An informal term for pubic lice.

Endemic—A condition that is always present in a given population, such as human lice infestation.

Host—An organism that is infected by a virus, bacterium, or parasite.

Infestation—A condition in which a parasite develops and multiplies on the body of its host rather than inside the body.

Insecticide—A pesticide that kills insects.

Lindane—An organic chloride, neurotoxic insecticide that kills lice.

Malathion—An organic phosphate, neurotoxic insecticide that kills lice.

Neurotoxin—A chemical compound that is toxic to the central nervous system.

Nit—The egg sac laid by adult female lice.

Nymph—The immature louse that hatches from the nit.

Pediculicide—Any substance that kills lice.

Pediculosis (plural, pediculoses)—A lice infestation.

Permethrin—A synthetic pyrethroid for killing lice.

Petroleum jelly or ointment—Petrolatum, a gelatinous substance obtained from oil that is used as a protective dressing.

Piperonyl butoxide—A liquid organic compound that enhances the activity of insecticides.

Pyrethrin, pyrethroid—Naturally-occurring insecticide extracted from chrysanthemum flowers. It paralyzes lice so that they cannot feed.

Wood's lamp—A special lamp that uses ultraviolet light to detect certain types of skin infections and infestations. It was invented in 1903 by a physicist named Robert Wood.

Causes and symptoms

Causes

The cause of lice infestations is the presence of head, body, or pubic lice on a person's body or in their clothing. The life cycle of lice helps to explain some of the symptoms of an infestation. When the nit or egg hatches, about 8–10 days after being laid, it produces an immature louse called a nymph. The nymph needs blood to survive. It has sucking mouth parts on its head that can pierce the skin and draw blood to feed on. Human lice feed about five times a day for 35 to 45 minutes at a time. The nymph becomes a mature adult about 10 days after hatching. Its complete life cycle is between 30 and 35 days in length.

Symptoms

Lice infestations are characterized by intense **itching** caused by an allergic reaction to a toxin in the lice saliva. The itching can interfere with sleep and concentration. Repeated bites can lead to generalized skin eruptions or inflammation. Scratching or scraping at the bites can cause **hives** or abrasions that may lead to bacterial skin infections. Swelling or inflammation of the neck glands are common complications of head lice.

Some symptoms of a lice infestation depend on the area of the body that is affected:

- Head lice: Itchy scalp due to an allergic reaction to the bites of the lice; small red bumps on the head or neck; sensation of something moving over the scalp; an irritated rash caused by scratching the itchy parts of the scalp.
- Body lice: Itching and a rash caused by an allergic reaction to the bites of the lice. A long-term infestation may cause discoloration of the skin of the waist area and upper thighs. There may also be open sores caused by scratching the itching areas; these raw areas can become infected by other disease organisms.
- Pubic lice: Itching in the genital area or other body areas with coarse hair (armpits, mustache area, eyebrows, eyelashes), and visible nits or lice crawling in the affected area. Crab lice in children may be an indication of sexual activity or abuse.

Diagnosis

Examination

The steady increase in all three types of lice infestations since 1980 means that the diagnosis and treatment of such infestations is one of the most common tasks in a general medical practice. A diagnosis of lice infestation can be made in the doctor's office by examining the skin, hair, pubic area, or clothing of the affected person. The doctor can collect nits from the hair by using a fine-toothed comb or remove lice from the body with a piece of cellulose tape. The organisms can then be studied under the microscope to determine the type of lice involved. Lice usually are diagnosed by the itching. However, itching may not occur until

WWW.BOOKBAZ.IR

several weeks after infestation, if at all. The tickling caused by moving lice may be noticeable. Definite diagnosis requires identification of lice or their nits.

Head lice may cause irritability in children. Scalp irritations or sores may be present. Although head lice in children are usually limited to the scalp, in adults, head lice can spread to eyebrows, eyelashes, mustaches, and beards. An adult louse may be visible as movement on the scalp, especially around the ears, nape of the neck, and center line of the crown—the warmest parts of the head. Since less than 20 mature lice may be present at a given time during infestation, the nits often are easier to spot. Nits vary in color from grayish-white to yellow, brown, or black. They are visible at the base or on the shaft of individual hairs. Applying about 10 oz (280 g) of isopropyl (rubbing) alcohol to the hair and rubbing with a white towel for about 30 seconds releases lice onto the towel for identification.

Body lice appear similar to head lice; however, they burrow into the skin and are rarely seen except on clothing, where they lay their nits in seams. Over time, body lice infestations can lead to a thickening and discoloring of the skin around the waist, groin, and upper thighs. Scratching may cause sores that become infected with bacteria or fungi.

Pubic lice usually appear first on genital hair, although they may spread to other body hair. In young children, pubic lice are usually seen on the eyebrows or eyelashes. Pubic lice appear as brown or gray moving dots on the skin. There are usually only a few live lice present and they move very quickly away from light. Their white nits can be seen on hair shafts close to the skin. Although pubic lice sometimes produce small, bluish spots called maculae ceruleae on the trunk or thighs, usually it is easier to spot scratching marks. Small dark-brown specks of lice excretion may be visible on underwear.

Since pediculicides (medications for treating lice) are usually strong insecticides with potential side effects, it is important to rule out other causes of scratching and skin inflammation. The oval-shaped head lice nits can be distinguished from dandruff because they are glued at an angle to the hair shaft. In contrast, flat, irregularly shaped flakes of dandruff shake off easily. A healthcare professional needs to distinguish between body lice and scabies—a disease caused by skin mites—and between pubic lice and **eczema**, a skin condition.

Tests

Another test that can be performed to diagnose lice infestations involves the use of a Wood's lamp, which is a device that uses ultraviolet light to detect lice, **fungal infections**, and a few other types of skin infections. The patient is taken into a dark room while the doctor shines the lamp on the area that may be infested. If lice or nits are present, they will glow greenish-yellow.

Patients diagnosed with an infestation of pubic lice may be given a blood test to check for HIV and other sexually transmitted diseases.

Treatment

Most treatments apply to all types of lice infestation and, particularly with head lice, treatments are an area of great controversy. The questionable safety and effectiveness of allopathic (fighting disease with remedies that produce effects different from those produced by the disease) treatments has spurred the search for alternative therapies. As of 2014, there is no single product or method that assures 100% destruction of the eggs and hatched lice after just one treatment. With any type of treatment, itching may not subside for several days.

Head lice

Most authorities believe that head lice should be treated immediately upon discovery. Before beginning any treatment:

- test a small scalp section for allergic reactions to the medication
- a vinegar rinse may help to loosen nits
- wash hair with regular shampoo

Treatments that are applied to the scalp and hair include:

- olive oil or petroleum ointment to smother the lice; cover the head with a shower cap, four to six hours per day for three to four days
- olive oil (three parts) and essential oil of lavender (one part)
- herbal shampoos or pomades
- a mixture of paw paw, thymol, and tea tree oil
- a combination of coconut oil, anise, and ylang ylang
- other mixtures of essential oils
- RID Pure Alternative, a nontoxic, hypoallergenic, dye and fragrance-free product
- a spray containing phenethyl propionate, cedar oil, peppermint oil, and sodium lauryl sulfate (LiceFreee)
- cocamide DEA (a lathering agent), triethanolamine (a local irritant), and disodium EDTA (a chelator), (SafeTek) is both a nontoxic pediculicide and a conditioner for combing out lice and nits

Cutting the hair or shaving the head may be effective. Aromatherapies also are available. Infested eyelashes and eyebrows should be treated with petroleum jelly for several days and the nits should be plucked off with tweezers or fingernails.

Body lice

Treatment for body lice is a thorough washing of the entire body and replacing infected clothing. Clothing and bedding should be washed at 140°F (60°C) and dried at high temperature, or dry-cleaned.

Pubic lice

A common herbal treatment for pubic lice consists of:

- oil of pennyroyal, *Mentha pulegium*, 25%
- oil of garlic, *Allium sativum*, 25%
- distilled water, 50%

The mixture is applied to the pubic hair once a day for three days. Anyone with pubic lice should be tested for other sexually transmitted diseases.

Nit removal

Neither alternative nor allopathic treatments will kill all lice nits. Hair and pubic lice nits must be removed manually to prevent re-infestation as the eggs hatch. Manual removal alone may effectively treat a lice infestation.

Before removing nits, one of the following procedures may be used:

- 50% vinegar rinse to loosen the nits
- wiping individual locks of hair from base to tip with a cloth soaked in vinegar
- 8% formic acid solution applied to the hair for 10 minutes, rinsed out, and towel-dried
- catching live lice with a comb, tweezers, fingernails, or by sticking them with double-sided tape
- enzymatic lice-egg remover

Furthermore, hair should be clean, damp, and untangled and hair conditioner should not be used on hair treated allopathically. Clothing should be removed and a towel placed between the hair and shoulders. Divide hair into 6 square-inch (6 sq.-cm.) sections. Clips or elastics can be used to divide long hair. This will help ensure that the entire scalp is inspected.

Nits are manually removed with:

- any fine-toothed comb, including pet flea combs
- a specialized nit comb (LiceMeister, LiceOut)
- a battery-powered vibrating or anti-static comb
- tweezers
- baby safety scissors
- fingernails

To comb out nits, comb along each hair section from scalp to tip. Between each passing, dip the comb in water and wipe with a paper towel to remove lice and nits. Hold the comb to the light to be sure it is clean. If necessary, clean comb with a tooth or fingernail brush or dental floss. Work under a good light using a magnifying glass if necessary. Do not rush—long, thick hair may take an hour to comb out thoroughly. Wash towels and clothing after combing. This treatment should be repeated at least twice a week for at least two weeks.

Reinfestation

Reinfestation occurs often with all types of lice due to:

- ineffective or incomplete treatment
- chemical-resistant lice
- failure to remove live nits
- failure to treat all infected household members, playmates, or sexual partners
- failure to remove nits from clothing, bedding, towels, or other items
- reinfestation from another source

Reinfestation with body or pubic lice can be prevented by washing underclothes, sleepwear, bedding, and towels in hot, soapy water and drying with high heat for at least 20 minutes. Clothing infected with body lice should be ironed under high heat. Sexual partners should be treated for public lice simultaneously and should re-examine themselves for several days.

To prevent head lice reinfestation:

- Repeat lice checks and nit removal daily until none are found.
- Notify school, camp, or day care center, and parents of playmates.
- Check and if necessary treat household members, playmates, schoolmates, school or daycare staff, and others in close contact with an infestation.
- Treat combs and brushes with rubbing alcohol, Lysol, or soapy water above 130°F (54°C).
- Wash all bedding, clothing, headgear, scarves, and coats with soapy water at 130°F (54°C) and dry with high heat for at least 20 minutes.
- Wash or vacuum stuffed animals and other toys.
- Vacuum all helmets, carpets, rugs, mattresses, pillows, upholstery, and car seats.

WWW.BOOKBAZ.IR

- Remove the vacuum cleaner bag after use, seal in a plastic bag, and place in the outside garbage.
- Non-washable items should be dry cleaned or sealed in a plastic bag for up to four weeks.
- Lice pesticide sprays for inanimate objects are toxic and are not recommended.
- Repeat treatment if necessary.

Infested eyelashes are treated with a thick coating of prescription petroleum ointment, applied twice daily for ten days.

Drugs

All types of lice are treated allopathically with insecticidal lotions, shampoos, or cream rinses. Experts disagree about the effectiveness and/or safety of pediculicides. Pediculicides do not kill nits, so nit removal and a second application in seven to 10 days may be necessary. Pediculicides can be poisonous if used improperly or too frequently and overuse can lead to the proliferation of chemically resistant lice. The residue may remain on the hair for several weeks and can cause skin or eye irritations.

Pediculicides should *not* be used:

- near broken skin, eyes, or mucous membranes
- in the bathtub or shower
- by pregnant or nursing women or children under two
- by those with allergies, asthma, epilepsy, or some other medical conditions

PYRETHROIDS. All U.S. Food and Drug Administration (FDA)-approved nonprescription pediculicides contain relatively safe and effective pyrethroids. Insecticidal pyrethrins (0.33%) (RID, A-200) are extracts from chrysanthemum flowers. Permethrin (1%) (Nix) is a more stable synthetic pyrethrin. Pyrethroid pediculicides usually contain 4% piperonyl butoxide.

To treat with pyrethroids:

- Apply for specified time, usually ten minutes.
- Thoroughly rinse out.
- Do not wash hair for one or two days after treatment.
- Do not use cream rinse, hair spray, mousse, gels, mayonnaise, or vinegar before or within one week after treatment. These products may reduce pediculicide effectiveness.

During the 1990s, as schools began requiring children to be lice and nit-free, the use of pyrethroids rose significantly and the FDA began receiving reports of ineffectiveness. The FDA ordered new labeling of pyrethroid pediculicides on the outside of the carton, in simpler language, and with more information in 2006. Permethrin sprays for treating mattresses, furniture, and other items are not recommended.

OTHER INSECTICIDES. Prescription insecticides are used when other lice treatments fail or cannot be used. These pesticides include:

- Malathion (0.5% in Ovide), a neurotoxic organophosphate, was withdrawn from the U.S. market due to an increase in malathion-resistant lice and re-introduced in 1999. It is foul-smelling and flammable. Sometimes infested clothing is treated with a 1% malathion powder. The chief advantage of malthion is that it is effective against lice that have developed resistance to lindane and permethrin.
- Lindane (1% or higher; Kwell), an organochloride neurotoxin, can induce seizures and death in susceptible people, even when used according to the directions. In 2003 the FDA required new labeling and a reduction in bottle size.
- Ivermectin (Stromectol), an oral treatment for intestinal parasites, is effective against head lice but has not been approved for that use by the FDA as of 2014. It is approved in Europe for the treatment of head lice, and a recent clinical trial reported in the *New England Journal of Medicine* in March 2010 that oral ivermectin is superior to malathion for difficult-to-treat head lice.

Prognosis

Despite the presence of chemically resistant lice and the thoroughness required to prevent reinfestation, essentially all lice infestations can be eradicated eventually. Lice infestations by themselves are not fatal; however, body lice are dangerous because they can transmit three potentially fatal illnesses: **typhus**, **relapsing fever**, and **trench fever**. Pubic lice are not known to spread other diseases as of 2014. In 2009, 25% of head lice from homeless persons in San Francisco were found to be carrying *Bartonella quintana*, the bacterium that causes trench **fever**. This finding suggests that head lice as well as body lice are potential carriers of **emerging diseases**.

Prevention

Prevention of lice infestation depends on adequate personal hygiene and the following public health measures:

- avoid sharing combs, brushes, hair accessories, hats, towels, or bedding
- check hair and scalp weekly for lice and nits
- limit the number of sexual partners

Regular lice checks in schools and "no nit" reentry policies have not been shown to be effective. The American Academy of Pediatrics, the Harvard School of Public Health, and the National Association of School Nurses recommend their elimination, although many healthcare professionals disagree.

Scientists have identified both the gene that enables head and body lice to digest blood and the gene that helps lice combat deadly infections, with the potential for new treatments and preventatives for lice infestation.

Lichen planus

Definition

Lichen planus is a chronic mucocutaneous (relating to the skin and mucous membrane) condition of unknown origin that produces rows of small, shiny, flat–topped, itchy pink or purple raised papules or lesions (bumps) or **rashes** (spots) on the wrists, forearms or lower legs, especially in middle-aged patients. It sometimes also affects the mucous membranes, such as those within the mouth and genitals. The name refers to the inflammatory appearance of the skin.

Demographics

The condition affects females more than males, in an approximate ratio of three to two. It also affects middle-aged people more often than younger or older people. Infants and children rarely get the condition. Lichen planus is found throughout the world and is equally distributed among races. It affects between one and two percent of the world' population. The majority of the people affected by licken planus consist of middle-aged women. People with **hepatitis C** or **cirrhosis** (liver scarring) are also more likely to get lichen planus.

Description

The condition is not contagious nor infectious. However, it is difficult to treat, with reoccurrences coming back for years even with proper treatment. Lesions are found on the skin, genitals, and in the mouth. Most cases resolve spontaneously within two years. These features usually characterize the affected skin: purple in color, shape of polygonal papules, without depth (flat to the skin's surface), and itchy but without any apparent reason (pruritic). They are most often located on the wrists and ankles. When the condition begins to heal, the skin turns a brownish or blue–black color, which may remain for a long time.

Causes and symptoms

No one knows what causes lichen planus, although some experts suspect that it is an abnormal immune reaction following a viral infection, probably aggravated by **stress**. The condition does not involve any known pathogens and it cannot be passed from one person to another (not contagious). The condition is similar to symptoms caused by exposure to arsenic, bismuth, gold, iodides, quinide, **diuretics**, or developers used in color photography. The rashes that it produces are called lichenoid reactions. These reactions are further classified as lichenoid mucositis (of the mucosa) or lichenoid **dermatitis** (of the skin). Either one can be caused by **heart disease**, arthritis, medications used to control high blood pressure, and reactions to **allergies**. Occasionally, lichen planus in the mouth appears to be an allergic reaction to medications, filling material, dental hygiene products, chewing gum, or candy.

Symptoms can appear suddenly, or they may gradually develop, usually as a rash on the insides of the wrists, forearms, ankles, or legs. The rash may also be present on the scalp, neck, lower back, nails of the fingers and toes, or on the mucous membranes of the nose, mouth, vagina, penis, and anus. Lesions on the skin may be preceded by a dryness and metallic taste or burning in the mouth.

Once lesions appear, usually in rows, they change over time into flat, glistening, purple lesions marked with white lines or spots. Color may change from purple to pink, and then to red. Mild to severe **itching** is common. White, lacy lesions are usually painless, but eroded lesions often burn and can be painful. A soreness or burning sensation can emerge when symptoms involve the mucous membranes. When the nails are affected, their appearance often becomes split, thin, and grooved. The nails may eventually be lost. Hair on the scalp, when lichen planus is apparent, becomes thin, with the scalp itself appearing red and irritated. All of the hair on the scalp may be lost. As the lesions clear up, they usually leave a brown or gray discoloration behind, especially in dark skinned people. Rashes on the nails or scalp may leave permanent scarring.

Lichen planus in the mouth, sometimes called oral lichen planus, occurs in six different forms with a variety of symptoms. They may appear as lacy-white streaks, white plaques, or eroded **ulcers**. The streaks consist of small, pale reddish, slightly raised bumps, often on the tongue or inside the cheeks. Often the gums are affected, so that the surface of the gum peels off, leaving the gums red and raw. The area around the mouth may be painful and tender, with a burning or itching sensation. It may also feel dry and have a metallic taste to it. Food and beverages may have a diminished taste to them.

Diagnosis

A medical history of the patient is gathered, along with the performance of a **physical examination**. A doctor can probably diagnose the condition simply from looking at the characteristic lesions, but a **skin biopsy**, usually from a punch biopsy test, may be needed to confirm the diagnosis. A punch biopsy test removes a tiny section of the deeper layers of the skin. The biopsy, which is of an average depth of 0.25 inch (6 millimeters), is examined under a microscope to detect whether lichen planus is present.

Treatment

There is no cure for lichen planus. Treatment, which is usually difficult and long-term, is aimed at easing symptoms. Itching can be treated with steroid creams and oral **antihistamines**. Cool compresses and baths containing colloidal oatmeal can also help. Cortisosteroid ointment may be applied to the skin for minor irritations. Severe lesions can be treated with **corticosteroids** by mouth, or combinations of photochemotherapy (such as PUVA) and griseofulvin. PUVA, which stands for psoralen (also called psoralene) plus UVA treatment, is used when the patient takes an oral dose of psoralen to sensitize the skin and then the skin is exposed to ultraviolet-A (UVA) light. Griseofulvin (also called grisovin) is an antifungal drug.

Immunosuppressant medications may also be used. Hydroxychloroquine (Plaquenil), an antimalaria drug, is sometimes provided to reduce inflammation. Tacrolimus (FK-506 or Fujimycin), an immunosuppressive drug, is often taken to reduce allergic symptoms. Immune-modulating medication, such as imiquimod (Aldara) or tacrolimus (Protoic) may also be used. Dapsone, which is often given to treat **acne**, is sometimes used too. Aloe vera is applied to help return the damaged skin to its normal state.

KEY TERMS

PUVA—A type of phototherapy that combines the oral or topical photosensitizing chemical psoralen, plus long–wave ultraviolet light-A (UVA).

Patients with lesions in the mouth may find that regular professional cleaning of the teeth and conscientious dental care improve the condition. Using milder toothpastes instead of tartar control products also seems to lessen the number of ulcers and makes them less sensitive. A combination of oral corticosteroids and extra-strength corticosteroid ointments applied to the affected areas are often used for mucous membranes.

Even though lichen planus may go away with treatment, it can come back, sometimes years later.

Prognosis

While lichen planus can be annoying, it is usually fairly benign and clears up on its own. It may take months to reach its peak, but it usually clears up within 18 months. Normally, lichen planus is non–cancerous. However, long-term lesions associated with lichen planus can result in increased risk from squamous cell carcinoma, which is a type of **skin cancer**.

Prevention

It is recommended that people with at increased risk from lichen planus do not use tobacco products, such as cigarettes, because tobacco adds to the risk of squamous cell carcinoma. Regular examinations are advised for people more likely to contract lichen planus so that any changes to mucous membranes or the skin can be regularly monitored by medical professionals.

Lichen simplex chronicus

Definition

Lichen simplex chronicus (LSC) is a chronic inflammation of the skin (**dermatitis**) characterized by small, round itchy spots that thicken and become leathery as a result of scratching. Various degrees of scaling also occur from repeated scratching or rubbing. The inflammation occurs most frequently in the following areas: scalp, outer lower part of lower leg, knee, wrist, ankle, side and back of neck, forearm, elbow, scrotum, vulva, anal area, upper eyelid, ear opening, and fold behind ear. The itchiness felt by the person may be so intense that he or she is unable to stop. Soon, the patient continues to scratch out of habit, when begins the progression of the brown, thick, leathery skin.

Demographics

The chronic inflammation can occur in any human. It is not known to occur more or less frequently with respect to race. Its exact frequency has not been identified by the medical community. However, it is more common in women than in men. It is also more prevalent in adults age 30 to 50 years. People with previous skin conditions or with a family history of skin disorders, such as **psoriasis** and **eczema**, are more likely to develop lichen simplex chronicus. People are not at risk from dying of lichen simplex chronicus.

Description

Also termed neurodermatis and scratch dermatitis, lichen simplex chronicus is the result of chronic skin irritation. Initial irritation causes **itching**, and in turn, itching causes scratching. Scratching usually leads to further irritation, which damages the skin. The possibility of infection is greatly increased when the outer layer of protective skin is broken. Skin usually repairs itself quickly. However, in the case of lichen simplex chronicus, healing skin causes more itching and more scratching causes a thickening of the skin (lichen). The small skin patches are usually one to 10 inches (3–25 cm) in diameter.

Some complications from the condition if present for long periods include bacterial skin infection, permanent scarring, and permanent changes in the color of the skin.

Causes and symptoms

The cause of lichen simplex chronicus is not known. It is seen as often being caused by constant rubbing of the skin, such as in disorders like psoriasis and eczema. It may also occur when something continually irritates the skin, such as clothing. It may also result when such conditions as **anxiety**, depression, or nervousness occurs. The rubbing begins the chain of events that leads from itching to scratching and then to the presence of leather-like skin patches. Children are susceptible to the disorder because they often rub and scratch their skin, such as when insect bites occur. Mentally disabled children that have repetitive motions as part of their disability are also at higher risk for contracting lichen simplex chronicus.

Symptoms include chronic itching, which is often accompanied by nervous tension. The appearance of scratch marks and leathery skin patches can be found anywhere on the body. A prolonged lichen simplex chronicus can result in brown-colored pigmentation at the site of irritation. Signs of infection include a yellowish, thick fluid coming from the excessively scratched areas. **Pain** may also be another sign of infection. Other symptoms include **skin lesions** that are often located on the wrist, neck, wrist, forearms, inner elbow, thighs, lower leg, back of knee, and rectum/anus area. The lesions are usually raw looking and darkened or reddened, and include scratch marks, defined borders, and extended skin lines.

Diagnosis

A dermatologist, a physician specializing in the study and treatment of skin disorders, can make a diagnosis after a visual examination. Specifically, the medical professional looks at the appearance of the skin, and determines the period that itching and scratching have occurred. A patch test, sometimes also called a contact delayed hypersensitivity allergy test, is used to eliminate other disorders that may be the cause. Small drops of various diluted chemicals are placed onto the skin to see if an allergic reaction occurs.

A skin lesion biopsy, also called a punch biopsy, may be needed to confirm a diagnosis of lichen simplex chronicus. The biopsy (a tiny piece of removed skin) is sent to a laboratory so it can be analyzed under a microscope. The result will confirm whether or not the condition is due to lichen simplex chronicus or another disorder such as **lichen planus**.

Treatment

Treatment of the itching is necessary to stop the scratching and resulting skin damage. There are a number of ways to stop itching. Perhaps the most important is to cut fingernails very short. Ice can substitute for the relief of scratching. Heat and fuzzy clothing worsen itching; cold and smooth clothing pacify it. If the itching is persistent, dressings may be applied to the affected areas.

Among the topical medications that relieve itching are a number of commercial preparations containing menthol, camphor, eucalyptus oil, and aloe. Topical cortisone is also available without a prescription. Some preparations also contain **antihistamines**, which penetrate intact skin poorly. All these medicines work better under occlusion, which means putting a waterproof barrier like a rubber glove, plastic wrap, or cloth dressing over them. For broken skin, **topical antibiotics** like bacitracin help prevent infection. These preparations should be used early to forestall further damage to the skin.

Reducing the buildup of thick skin or thickened lesions may require medicines that dissolve or melt keratin, the major chemical in skin's outer layer. These keratolytics include urea, lactic acid, and salicylic acid. Lotions or soaps containing coal tar may also be recommended.

Resistant cases of lichen simplex chronicus will often respond to cortisone-like drugs injected directly into the lesions.

Sedatives or tranquilizers may be prescribed to combat the nervous tension and anxiety that often accompanies the condition.

In addition, counseling with a dermatologist may be necessary to minimize or eliminate the need to scratch and itch. Consultation with an allergist may also be needed. Specific psychological counseling in **stress** management or behavior modification should be sought for people with anxiety and stress.

Prognosis

Diligent adherence to treatment is usually rewarded with a resolution of the condition. The original cause of itching may be gone, or it may reappear. Preventive treatment in its early stages will arrest the process. Reducing stress and anxiety in one' life will help to minimize or eliminate the problem.

KEY TERMS

Antihistamine—A chemical that interferes with the action of histamine. Histamine is part of an inflammatory response and helps to cause itching.

Callus—Thickened skin due to chronic rubbing or irritation.

Lesion—Abnormal change in tissue caused by localized disease.

Prevention

Ways to prevent lichen simplex chronicus include keeping nails cut close so less damage is done to the skin when scratching occurs. Also, cover areas prone to scratching, especially if they are unconsciously scratched while sleep. Use over-the-counter creams or medications to eliminate the itchiness. Prevent dry skin by using moisturizing creams and ointments. Also, take cool baths filled with baking soda, colloidal oatmeal, or other similar ingredients that help to relieve skin irritants. When using cleansing products, such as clothing detergents, choose ones that do not contain perfumes and dyes. Maintain a healthy lifestyle that includes reducing stress and anxiety.

Life support

Definition

Life support refers to a spectrum of techniques and therapies used to maintain life after the failure of one or more vital organs. When someone is critically injured or seriously ill, life-saving techniques and therapies (such as a feeding tube, organ transplantation, heart and lung bypass machine, **cardiopulmonary resuscitation** [CPR], dialysis, defibrillator, and artificial pacemaker) are used in the attempt to sustain and save the patient' life. Such measures are often performed in such places as an operating room, emergency room (ER), intensive care unit (ICU), and ambulance. However, as such measures become more technically advanced, some become available in every day places. One such device is called the portable defibrillator, or automated external defibrillator. Bought by companies and governments, they are often ready to be used at a moment's notice in business settings and public areas.

Purpose

A patient requires life support when one or more vital organs fail, due to causes such as **trauma**, infection, cancer, **heart attack**, or chronic disease. Among the purposes of life support are to:

- Establish and maintain the ABCs of resuscitation—airway, breathing, and circulation.
- Restore the patient's homeostasis—the internal chemical and physical balance of the body.
- Protect the patient from complications of the underlying disease and its treatment.

The ABCs of life support is supported by a part of medical care that is commonly called basic life support (BLS). Within BLS, the medical professionals are called upon to care for patients with life-threatening illnesses and injuries until the patients can be provided with more comprehensive medical care. For instance, medical personnel inside an ambulance at the scene of a traffic accident are one type of person involved in BLS. These people receive BLS training in order to be certified at their position. Other people trained in BLS include firefighters, police officers, teachers, and security guards. Specific portions of the training involve guidelines of action that are to be used when coming across specific emergencies such as **drowning**, massive bleeding, or cardiac arrest. Once the BLS personnel transport the patient to the hospital or other medical facility, the next phase of medical care is begun—that of the advanced life support (ALS).

Precautions

Patients and families need to recognize that life support is an extremely painful, expensive, and emotionally wrenching experience. Life support exposes a patient to vast risks of further medical complications, and offers no guarantee of a positive outcome. Even in successful cases, recovery may be slow and frustrating.

Description

Successful life support begins with establishing the ABC's of resuscitation—airway, breathing, and circulation.

The airway refers to a clear and unobstructed passageway for air (primarily oxygen) to enter the lungs from outside the body and for primarily carbon dioxide to exit the lungs through the mouth and nose. The patient's airway may become blocked by:

- Foreign body obstruction, as by food or dentures
- Injury-related damage and swelling, as from a wound or surgery
- Loss of protective reflexes due to coma of any origin

Life support may begin with basic cardiopulmonary resuscitation (CPR), as in cases of cardiac arrest. Thereafter, the most common technique used to create a secure airway is insertion of an endotracheal (ET) tube through the mouth or nose into the windpipe (trachea). An alternative method of securing an airway is by **tracheotomy**, a surgical procedure in which a tube is inserted into the trachea through an incision made in the base of the throat. Of the two options, placement of an ET tube is usually quicker and more convenient, and thus occurs much more commonly. Doctors perform a tracheotomy when they cannot establish an ET airway, or when the patient will require an artificial airway for more than a week or two.

Breathing refers to the movement of air in and out of the lungs (respiration). Inadequate breathing may result from:

- Heart disease, as in congestive heart failure
- Primary diseases of the lungs, such as pneumonia, asthma, or emphysema
- Coma of any cause, such as narcotic overdose or stroke
- Muscle fatigue or neuromuscular disease (spinal cord injury or polio)
- Pain, from rib fractures or surgery on the chest

When the patient cannot breathe sufficiently, the physician will use a ventilator, a machine that pumps air in and out of the patient's lungs. For many doctors and members of the public, the term "life support" calls up the image of an ET tube and ventilator.

Circulation refers to the adequate flow of blood around the body from the heart to vital organs. The blood delivers oxygen to all cells of the body and removes carbon dioxide from all cells. Circulation can fail due to:

- Primary disease of the heart (heart attack)
- Blood loss (trauma or internal bleeding of any cause)
- Severe infection (sepsis)
- Drug reactions or overdoses
- Extreme allergic reaction
- Severe dehydration (gastroenteritis or heat-related illness)

In order to ensure adequate circulation, the patient will require one or more intravenous (IV) tubes (catheters). The IVs may include both the short needle and tube commonly used in the hand or forearm, and longer catheters inserted into the larger and more central veins of the body. Catheters inserted into these larger veins are known as central lines. Through the IVs the patient receives fluids, drugs, and blood transfusions as needed to support the circulation.

Once the ABC's are secure, life support is directed at maintaining homeostasis, the body's delicate chemical and physical balance. In a healthy person, the body keeps precise control over many components of its makeup, such as its fluids, nutrients, and pressures. When vital organs fail, the body can no longer regulate these components, and the doctor must take steps to restore the normal state.

Preserving the body's internal equilibrium requires careful monitoring of innumerable indicators of the patient's well-being. These indicators include:

- Vital signs (heartbeats per minute, breaths per minute, blood pressure, body temperature, and weight)
- Fluids (input and output of the body)
- Blood cell counts
- Chemical substances of the body (sodium, potassium, sugar, and many others)
- Pressures in the circulation, lungs, and perhaps even the brain
- Presence of germs (bacteria, fungi) causing infection in body systems (lungs, blood, urine)

This intensive monitoring usually takes place in an intensive care unit (ICU) or critical care unit (CCU) and requires:

- Specialized physicians, such as cardiologists, intensivists, and surgeons
- Highly-skilled nursing care, often one nurse per patient around-the-clock
- Extensive support staff, such as respiratory therapists, laboratory technicians, radiology technicians, dieticians, and pharmacists
- Constant measurement of basics such as pulse, heart rhythm, and oxygen level in the blood
- Frequent inspection of the patient's alertness, color, and level of pain
- Use of catheters in the veins and arteries to withdraw blood samples and measure pressures in the circulation
- Use of tubes in the bladder (Foley catheter), stomach (nasogastric tube), and other body cavities
- Frequent laboratory tests on blood, urine, drainage from wounds, and other body specimens
- X-ray, ultrasound, computerized tomography (CT), and other imaging procedures
- Electrocardiograms

The treatments of life support include:

- Oxygen
- Intravenous fluids with sugar and basic salts
- Drugs to improve circulation and other body functions
- Antibiotics
- Transfusions
- Surgery
- Nutritional supplements by vein or stomach tube
- Tubes in body cavities (chest or abdomen) to relieve fluid buildup
- Dialysis
- Pacemaker

WWW.BOOKBAZ.IR

- Electrical defibrillation
- Various machines to assist heart or lung function
- Transplantation of organs or mechanical substitutes (artificial heart)
- Sedation or even temporary paralysis to enable the patient to tolerate these procedures

Preparation

The need for life support may arise suddenly and with little warning. All people should discuss in advance with family and doctor their wishes for the use of life support should a medical crisis develop. The doctor will note the preferences in the patient's record. Patients should sign documents such as an Advance Directive and Durable Power of Attorney for Health Care to express their wishes and designate a surrogate decision-maker in case of incapacitation.

Physicians and medical care providers must anticipate the possibility that a patient will require life support, perhaps suddenly. In preparation, doctors and medical staff must:

- Receive training in resuscitation skills
- Monitor patients carefully
- Maintain proper supplies and equipment
- Discuss in advance with patients and patients' families whether or not to begin life support

Aftercare

If a patient survives life support treatments, doctors will cautiously try to wean the patient from the support systems. Being able to breathe adequately without the ventilator is one major hurdle. Patients commonly fail in their first attempts to breathe on their own, often tiring out after a few hours. Thus, the doctor will reconnect the ventilator, give the patient a rest, and try again in a day or two.

As the patient regains organ function, there is less need for monitors, tests, and treatments that require an intensive care setting. The doctor may transfer the patient to a lower level of hospital care, a skilled nursing facility (SNF), or perhaps directly to home. Physical and occupational therapists may help the patient improve strength and endurance. The patient will receive continuing care from the primary doctor and specialists as needed. The patient may require prescription drugs, assist devices, and psychological therapists.

Risks

The risks and consequences of life support are enormous. These risks include:

- Physical dangers
- Emotional suffering
- Financial costs
- Societal discord

The physical dangers of life support encompass all the hazards of the patient's underlying disease and treatments. Among these risks are:

- Permanent damage to the brain, kidneys, and other vital organs caused by poor circulation or low oxygen content of the blood
- Direct damage to organs from use of medical instruments and procedures
- Infections, often with organisms that are highly resistant to antibiotics
- Abnormal blood clots
- Skin ulcers from lying immobilized for long periods
- Extreme pain
- Exposure of medical personnel to communicable diseases

The emotional consequences of life support touch patients, families, and medical caregivers. These repercussions arise from:

- The frightening environment of an ICU
- The need to make life-and-death decisions
- The anger, guilt, and grief that relate to life-threatening illness
- The fact that many lengthy and difficult treatments will end in failure

The financial costs of life support are huge. A single day of life support costs many thousands of dollars. These expenses fall on individual payers, insurance companies, health plans, and governments. All such payers face difficult decisions regarding the allotment of money for such treatment, especially in cases that are likely to be futile.

Although the removal of life support from a seriously ill or injured person may be seen as a rare occurrence in society, it has been found to be relatively common. In fact, in a 2008 study funded by the National Institute of Nursing Research, and appearing in the *American Journal of Respiratory and Critical Care Medicine*, a gradual removal of life support, called sequential withdrawal, was found to be quite common. In fact, Dr. J. Randall Curtis, the principal investigator of the study, states that the sequential

Light therapy

Definition

Light therapy, or **phototherapy**, is the administration of doses of bright light in order to treat a variety of sleep and **mood disorders**. It is most commonly used to re-regulate the body's internal clock and/or relieve depression.

Purpose

Light therapy is most often prescribed to treat **seasonal affective disorder**, a form of depression most often associated with shortened daylight hours in northern latitudes from the late fall to the early spring. It is also occasionally employed to treat such sleep-related disorders as **insomnia** and **jet lag**. Recently, light therapy has also been found effective in the treatment of such nonseasonal forms of depression as **bipolar disorder**. One 2001 study found that bright light reduced depressive symptoms 12–35% more than a placebo treatment in nine out of 10 randomized controlled trials.

WWW.BOOKBAZ.IR

When used to treat SAD or other forms of depression, light therapy has several advantages over prescription antidepressants. Light therapy tends to work faster than medications, alleviating depressive symptoms within two to 14 days after beginning light therapy as opposed to an average of four to six weeks with medication. And unlike antidepressants, which can cause a variety of side effects from nausea to concentration problems, light therapy is extremely well tolerated. Some side effects are possible with light but are generally not serious enough to cause discontinuation of the therapy.

There are several other different applications for light therapy, including:

- Full-spectrum/UV light therapy for disorders of the skin. A subtype of light therapy that is often prescribed to treat skin diseases, rashes, and jaundice.
- Cold laser therapy. The treatment involves focusing very low-intensity beams of laser light on the skin, and is used in laser acupuncture to treat a myriad of symptoms and illnesses, including pain, stress, and tendinitis.
- Colored light therapy. In colored light therapy, different colored filters are applied over a light source to achieve specific therapeutic effects. The colored light is then focused on the patient, either with a floodlight which covers the patient with the colored light, or with a beam of light that is focused on the area of the illness.
- Back of knee light therapy. According to a 1998 study published in the journal *Science*, the area behind the human knee known as the popliteal region contains photoreceptors that can help to adjust the body's circadian rhythms. The authors of the study found that they could manipulate circadian rhythms by focusing a bright light on the popliteal region. Further studies are underway to determine the efficacy of this treatment on disorders such as SAD and diabetic nerve pain.

Description

Light therapy is generally administered at home. The most commonly used light therapy equipment is a portable lighting device known as a light box. The light box may be a full-spectrum box, in which the lighting element contains all wavelengths of light found in natural light (including UV rays), or it may be a bright light box, in which the lighting element emits non-UV white light. The box may be mounted upright to a wall, or slanted downwards towards a table.

The patient sits in front of the box for a prescribed period of time (anywhere from 15 minutes to several hours). For patients just starting on the therapy, initial sessions are usually only 10–15 minutes in length. Some patients with SAD undergo light therapy session two or three times a day, others only once. The time of day and number of times treatment is administered depends on the physical needs and lifestyle of the individual patient. If light therapy has been prescribed for the treatment of SAD, it typically begins in the fall months as the days begin to shorten, and continues throughout the winter and possibly the early spring. Patients with a long-standing history of SAD are usually able to establish a time-table or pattern to their depressive symptoms, and can initiate treatment accordingly before symptoms begin.

The light from a slanted light box is designed to focus on the table it sits upon, so patients may look down to read or do other sedentary activities during therapy. Patients using an upright light box must face the light source, and should glance toward the light source occasionally without staring directly into the light. The light sources in these light boxes typically range from 2,500–10,000 lux (in contrast, average indoor lighting is 300–500 lux; a sunny summer day is about 100,000 lux).

Light boxes can be purchased for between $200 and $500. Some healthcare providers and healthcare supply companies also rent the fixtures. This gives a patient the opportunity to have a trial run of the therapy before making the investment in a light box. Recently, several new light box products have become available. Dawn simulators are lighting devices or fixtures that are programmed to turn on gradually, from dim to bright light, to simulate the sunrise. They are sometimes prescribed for individuals who have difficulty getting up in the morning due to SAD symptoms. Another device known as a light visor is designed to give an individual more mobility during treatment. The visor is a lighting apparatus that is worn like a sun visor around the crown of the head. Patients with any history of eye problems should consult their healthcare professional before attempting to use a light visor.

Origins

Light, both natural and artificial, has been prescribed throughout the ages for healing purposes. Sunlight has been used medicinally since the time of the ancient Greeks; Hippocrates, the father of modern medicine, prescribed exposure to sunlight for a number of illnesses. In the late nineteenth and early twentieth centuries, bright light and fresh air were frequently prescribed for a number of mood and **stress** related disorders. In fact, prior to World War II (1939–1945),

hospitals were regularly built with solariums, or sun rooms, in which patients could spend time recuperating in the sunlight.

Precautions

Patients with eye problems should see an ophthalmologist regularly both before and during light therapy. Because UV rays are emitted by the light box, patients taking photosensitizing medications should consult with their healthcare provider before beginning treatment. In addition, patients with medical conditions that make them sensitive to UV rays should also be seen by a healthcare professional before starting phototherapy.

Patients beginning light therapy for SAD may need to adjust the length, frequency, and timing of their phototherapy sessions in order to achieve the maximum benefits. Patients should keep their healthcare provider informed of their progress and the status of their depressive symptoms. Occasionally, additional treatment measures for depression (e.g, antidepressants, herbal remedies, **psychotherapy**) may be recommended as an adjunct, or companion treatment, to light therapy.

Preparation

Full-spectrum light boxes do emit UV rays, so patients with sun-sensitive skin should apply a sun screen before sitting in front of the box for an extended period of time.

Risks

Some patients undergoing light therapy treatments report side effects of eyestrain, headaches, insomnia, **fatigue**, **sunburn**, and dry eyes and nose. Most of these effects can be managed by adjusting the timing and duration of the light therapy sessions. A strong sun block and eye and nose drops can alleviate the others. Long-term studies have shown no negative effects to eye function of individuals undergoing light therapy treatment.

A small percentage of light therapy patients may experience hypomania, a feeling of exaggerated, hyperelevated mood. Again, adjusting the length and frequency of treatment sessions can usually manage this side effect.

Research and general acceptance

Light therapy is widely accepted by both traditional and complementary medicine as an effective treatment for SAD. The exact mechanisms by which the treatment works are not known, but the bright light employed in light therapy may act to readjust the body's circadian rhythms, or internal clock. Other popular theories are that light triggers the production of serotonin, a neurotransmitter believed to be related to **depressive disorders**, or that it influences the body's production of melatonin, a hormone that may be related to circadian rhythms. A recent British study suggests that dawn simulation, a form of light therapy in which the patient is exposed to white light of gradually increasing brightness (peaking at 250 lux after 90 minutes) may be even more effective in treating depression than exposure to bright light. Dawn simulation is started around 4:30 or 5 a.m., while the patient is still asleep.

Wide-spectrum UV light treatment for skin disorders such as **psoriasis** is also considered a standard treatment option in clinical practice. However, such other light-related treatments as cold laser therapy and colored light therapy are not generally accepted, since few or no scientific studies exist on the techniques.

Training and certification

Psychiatrists, psychologists, and other mental healthcare professional prescribe light therapy treatment for SAD. Holistic healthcare professionals and light therapists who specialize in this treatment are also available; in some states, these professionals require a license, so individuals should check with

KEY TERMS

Dawn simulation—A form of light therapy in which the patient is exposed while asleep to gradually brightening white light over a period of an hour and a half.

Lux—The International System unit for measuring illumination, equal to one lumen per square meter.

Neurotransmitter—A chemical in the brain that transmits messages between neurons, or nerve cells.

Seasonal affective disorder (SAD)—A mood disorder characterized by depression, weight gain, and sleepiness during the winter months. An estimated 4–6% of the population of Canada and the northern United States suffers from SAD.

Serotonin—A neurotransmitter that is involved in mood disorders as well as transmitting nerve impulses.

Lipase test

Definition

The lipase test is a blood test performed to determine the serum level of a specific protein (enzyme) involved in digestion. Lipase is an enzyme produced by the pancreas, which is a large gland situated near the stomach. Lipase works to break down a certain type of blood lipid (**triglycerides**) into fatty acids.

Lipase appears in the blood together with another enzyme called amylase following damage to or diseases affecting the pancreas. It was once thought that abnormally high lipase levels were associated only with diseases of the pancreas. Other conditions are now known to be associated with high lipase levels, especially kidney failure and intestinal obstruction. Diseases involving the pancreas, however, produce much higher lipase levels than diseases of other organs. Lipase levels in pancreatic disorders are often 5–10 times higher than normal.

Purpose

The lipase test is most often used in evaluating inflammation of the pancreas (**pancreatitis**), but it is also useful in diagnosing kidney failure, intestinal obstruction, **mumps**, and peptic **ulcers**. Doctors often order amylase and lipase tests at the same time to help distinguish pancreatitis from ulcers and other disorders in the abdomen. If the patient has acute (sudden onset) pancreatitis, the lipase level usually rises somewhat later than the amylase level—about 24–48 hours after onset of symptoms—and remains abnormally high for 5–7 days. Because the lipase level peaks later and remains elevated longer, its determination is more useful in late diagnosis of acute pancreatitis. Conversely, however, lipase levels are not as useful in diagnosing chronic pancreatic disease.

Precautions

Patients should be asked whether they are taking certain prescription drugs that can affect the accuracy of the lipase test. Drugs that can cause elevated lipase levels include bethanechol, cholinergics, codeine, indomethacin, meperidine, methacholine, and morphine. Drugs that may decrease levels include **calcium** ions.

Description

A lipase test is performed on a sample of the patient's blood, withdrawn from a vein into a vacuum tube. The procedure, which is called a venipuncture, takes about five minutes.

Preparation

The patient should have nothing to eat or drink for 12 hours before the lipase test.

Results

Reference values for lipase determination are laboratory- and method-specific. In general, normal results are usually less than 200 units/L (triolein methods by titration or turbidimetry).

Increased lipase levels are found in acute pancreatitis, chronic relapsing pancreatitis, and pancreatic cancer. High lipase levels also occur in certain liver diseases, kidney failure, bowel obstruction, peptic ulcer disease, and tumors or inflammation of the salivary glands.

KEY TERMS

Amylase—A digestive enzyme that breaks down starch.

Lipid—A greasy organic compound that cannot be dissolved in water. Triglycerides, which are broken down by lipase, are one type of blood lipid.

Pancreas—An elongated gland situated across the back of the abdomen behind the stomach. It secretes both digestive enzymes and hormones. Pancreatic hormones regulate the level of sugar in the blood.

Pancreatitis—Inflammation of the pancreas, frequently caused by gallstones, alcohol abuse, viral infection, or injury.

Turbidimetry—A technique of measurement that analyzes the amount of sediment in a liquid.

Risks

Risks for this test are minimal, but may include slight bleeding from the puncture site, a small bruise or swelling in the area, **fainting**, or feeling lightheaded.

Lipidoses

Definition

Lipidoses are heredity metabolic disorders, passed from parents to their children, characterized by defects of the digestive system that impair the way the body uses fats (a type of lipid) from the diet. When the body is unable to properly digest fats, one or more enzymes used to metabolize lipids are not produced in sufficient amounts or are improperly produced. Consequently, lipids accumulate in body tissues in abnormal amounts. Lipids are molecules that include fats, waxes, oils, fat-soluble **vitamins**, sterols (such as estrogen and **cholesterol**), and other related compounds whose primary task is to store energy. Consequently, lipidoses are also called by the name of lipid storage disorders or diseases. When lipids excessively accumulate over time they can eventually lead to cell and tissue damage, especially affecting the brain, peripheral nervous system, spleen, liver, and bone marrow.

Demographics

This group of diseases is inherited from one or both parents. In each case of lipidoses, the parent carries a gene that is unable to regulate a particular protein. In some cases, neither parent has the disorder but passes it on to their offspring, equally affecting both males and females. In other instances, the mother carries the damaged gene and passes it on to her offspring, with the males more severely affected by the disorder than the females.

Description

The digestion, storage, and use of fats from foods is a complex process that involves hundreds of chemical reactions in the body. In most people, the body is already programmed by its genetic code to produce all of the enzymes and chemicals necessary to carry out these functions. These genetic instructions are passed from parents to their offspring during reproduction.

People with lipidoses are born without the genetic codes needed to tell their bodies how to complete a particular part of the fat digestion process. In most of these disorders, the body does not produce a certain enzyme or chemical. Over 30 different disorders of fat metabolism are related to genetic defects. Although the defects are passed from parents to children, the parents often do not have the disorders themselves.

The symptoms, available treatments, and long-term consequences of these conditions vary greatly. Some of the conditions become apparent shortly after the infant is born; in others, symptoms may not develop until adulthood. For most of the lipidoses, diagnosis is suspected based on the symptoms and family history. Blood tests, urine tests, and tissue tests can be used to confirm the diagnosis. **Genetic testing** can be used, in some cases, to identify the defective gene. Some of these disorders can be controlled with changes in the diet, medications, or enzyme supplements. For many, treatment is not available. Some may cause death in childhood or contribute to a shortened life expectancy. Some of the most common or most serious lipidoses are discussed below.

WWW.BOOKBAZ.IR

Fabry's disease

Causes and symptoms

Approximately one in every 40,000 males is born with Fabry's disease, which is also called Fabry disease and alpha-galactosidase-A deficiency. This condition has an X-linked, recessive pattern of inheritance, meaning that the defective gene is carried on the X chromosome. A female who carries a defective recessive gene on one of her two X chromosomes has a 50% chance of passing the defective gene to her sons who will develop the disorder associated with the defective gene (a male receives one X chromosome from his mother and one Y chromosome from his father). She also has a 50% chance of passing the defective recessive gene to her daughters who will be carriers of the disorder (like their mother). Some female carriers of Fabry's disease show mild signs of the disorder, especially cloudiness of the cornea.

The gene that is defective in Fabry's disease causes a deficiency of the enzyme alpha-galactosidase A. Without this enzyme, fatty compounds start to line the blood vessels. The collection of fatty deposits eventually affects blood vessels in the skin, heart, kidneys, and nervous system. The first symptoms in childhood are **pain** and discomfort in the hands and feet brought on by **exercise**, **fever**, **stress**, or changes in the weather. A raised rash of dark red-purple noncancerous, spots (called angiokeratomas) is common, especially on skin between the waistline and the knees. Other symptoms include a decreased ability to sweat and changes in the cornea or outer layer of the eye. Other symptoms include gastrointestinal problems, heart enlargement, and progressive kidney damage. Although the disease begins in childhood, it progresses very slowly. Kidney and heart problems develop in adulthood.

Diagnosis

The diagnosis can be confirmed by a blood test to measure for alpha-galactosidase A. Women who are carries of the defective gene can also be identified by a blood test.

Treatment

Treatment focuses on prevention of symptoms and long-term complications and slowing down the progression of the disease. Daily doses of phenytoin **sodium** (Phenytek, Dilantin, Infatabs), diphenylhydantoin (Dilantin), or carbamazapine (Tegretol) can prevent or reduce the severity of pain in the hands and feet associated with the condition. To help with gastrointestinal problems, metoclopramide (Maxolon, Primperan, Pramin) may be given and, to help digest fats, the nutritional supplement called Lipisorb may be provided. A low-sodium, low-protein diet may be beneficial to those patients who have some kidney complications. If kidney problems progress, **kidney dialysis** or **kidney transplantation** may be required. Enzyme replacement therapy is currently being explored at helping to ease pain, reduce storage problems, and to improve organ capabilities.

Prognosis

Although patients with Fabry's disease usually survive to adulthood, they are at increased risk for **stroke**, heart attacks, and kidney damage. They usually die prematurely from complications of these high-risk conditions.

Drugs such as phenytoin and carbamazepine are often prescribed to treat pain that accompanies Fabry's disease. Metoclopramaide or Lipisorb (a nutritional supplement) can ease gastrointestinal distress that often occurs in Fabry's patients, and some individuals may require kidney transplant or dialysis. Recent experiments indicate that enzyme replacement can reduce storage, ease pain, and improve organ function in patients with Fabry's disease.

Gaucher disease

Causes and symptoms

Gaucher (pronounced go-shay) disease, also called Gaucher's disease, is the most common of the lipid storage disorders. It is found in populations all over the world (20,000 to 40,000 people have a type of the disease), and it occurs with equal frequency in males and females. **Gaucher disease** has a recessive pattern of inheritance, meaning that a person must inherit a copy of the defective gene from both parents in order to have the disease. The genetic defect causes a deficiency of the enzyme glucocerebrosidase that is responsible for breaking down a certain type of fat and releasing it from fat cells. These fat cells begin to crowd out healthy cells in the liver, spleen, bones, and nervous system. Symptoms of Gaucher disease can start in infancy, childhood, or adulthood.

Three types of Gaucher disease have been identified, but there are many variations in how symptoms develop. Type 1 (non-neuropathic type) is the most common and affects both children and adults. It occurs much more often in people of Eastern European and Russian Jewish (Ashkenazi) ancestry, affecting 1 out of every 450 live births. The first signs of the disease include an enlarged liver and spleen, causing the abdomen to swell. Children with this condition may be shorter than the normal height. Other

symptoms include tiredness, pain, bone deterioration, bone lesions, broken bones, lymph node swelling, anemia, low blood **platelet count**, and bruising. It also may include yellow spots on the eyes and a brownish color to the skin. People with Gaucher disease are more prone to infections than are other people. Type 2 Gaucher disease (acute infantile neuropathic type) is more serious. It normally begins within the first few months after birth. Symptoms, which are similar to those in Type 1, progress rapidly, but also include nervous system damage, limb rigidity, and decreased ability to swallow or suck. Symptoms of Type 3 Gaucher disease (chronic neuronopathic type) begin during early childhood with symptoms like Type 1. Unlike Type 2, the progress of the disease is slower, although it also includes nervous system damage. Anemia, respiratory problems, and poor coordination are some of its specific symptoms.

Diagnosis

Gaucher disease may be suspected based on symptoms and is confirmed with a blood test for levels of the enzyme. Samples of tissue from an affected area may also be used to confirm a diagnosis of the disease.

Treatment

The symptoms of Gaucher disease in Type 1 and Type 3 Gaucher disease can be stopped and even reversed by treatment with injections of enzyme replacements. Such treatment has been found to counter many of the symptoms such as abnormal blood count, and liver and spleen size. Two enzyme drugs currently available are alglucerase (Ceredase) and imiglucerase (Cerezyme). Other treatments address specific symptoms such as anemia, broken bones, or pain. Type 1 and Type 3 Gaucher disease often results in brain and nervous system damage. There is not a way to reverse such damage.

Prognosis

The pain and deformities associated with symptoms can make coping with this illness very challenging for individuals and families. With treatment and control of symptoms, people with Type 1 Gaucher disease may lead fairly long and normal lives. Most infants with Type 2 die before the age of 2 years. Children with Type 3 Gaucher disease may survive to adolescence and early adulthood.

Krabbe's disease

Causes and symptoms

Krabbe's disease, also called Krabbe disease, is caused by a deficiency of the enzyme galactoside beta-galactosidase. It has a recessive pattern of inheritance and is believed to occur in 1 of 40,000 births in the United States. This condition, which is also called globoid cell leukodystrophy or Krabbe leukodystrophy, is characterized by acute central and peripheral nervous system degeneration. It develops in early infancy with initial symptoms of irritability, **vomiting**, and episodes of partial unconsciousness. Symptoms progress rapidly to seizures, muscle weakness, difficulty swallowing, blindness, deafness, **intellectual disability** (ID), and **paralysis**. Other symptoms include muscle weakness,

Treatment

A cure for Krabbe's disease is not available. Treatment is supportive at best, with actions that help to relieve symptoms. Some clinical trials have shown that children who receive umbilical cord blood stem cells from non-family members before any symptoms are present develop lessened neurological impairment than other children with the disease. Bone marrow transplants have also been tried in the more modest cases of Krabbe's disease.

Prognosis

Children born with Krabbe's disease die in infancy, usually before the age of 2 years. As shown by recent trials, children who have received umbilical cord blood stem cells or bone marrow transplants before symptoms are present show better prognosis than other children with the disease. People who get the disease later in later usually have a less severe form of it and live longer, too.

Niemann-Pick disease

Causes and symptoms

At least five different forms of Niemann-Pick disease (NPD) have been identified. The different types seem to be related to the activity level of the enzyme sphingomyelinase. In patients with Types A and B NPD, there is a build up of sphingomyelin in cells of the brain, liver, spleen, kidney, and lung. Type A is the most common form of NPD and the most serious, with death usually occurring by the age of 18 months. Symptoms develop within the first few months of life and include poor appetite, failure to grow, enlarged liver and spleen, and the appearance of cherry red spots in the retina of the eye. Type B (also labeled juvenile onset) develops in infancy or childhood with symptoms of mild liver or spleen enlargement and lung problems. Some adults with this form (Type E) may also show a loss of muscle coordination. Types C or D

WWW.BOOKBAZ.IR

NPD are related to cholesterol transfer out of cells. Children with Types C or D grow normally in early childhood, but eventually develop difficulty in walking and loss of muscle coordination. Ultimately, the nervous system becomes severely damaged and these patients die. Type C occurs in any population, while Type D has been identified only in patients from Nova Scotia, Canada.

Diagnosis

Diagnosis is confirmed by analyzing a sample of tissue. Prenatal diagnosis of Types A and B of NPD can be done with **amniocentesis** or **chorionic villus sampling**.

Treatment

There is not a cure for Niemann-Pick disease. Treatment consists of supportive care to deal with symptoms and the development of complications. **Bone marrow transplantation** is being investigated as a possible treatment for Type B. So far, the results have shown promise, but additional trials are necessary. Low-cholesterol **diets** may be helpful for patients with Types C and D, but clinical trials have not been promising.

Prognosis

Patients with Type A NPD usually die within the first year and a half of life, usually from infection or neurological problems. Type B patients generally live to adulthood but suffer from significant liver and lung problems. They usually require supplemental oxygen due to decreased function in their lungs. Bone marrow transplants have been attempted with such Type B patients. With Types C and D NPD, there is significant nervous system damage leading to severe **muscle spasms**, seizures, and eventually, to **coma** and death. Some patients with Types C and D die in childhood, while less severely affected patients may survive to adulthood.

Refsum's disease

Causes and symptoms

Refsum's disease, also called Refsum disease and Adult Refsum disease (ARD), has a recessive pattern of inheritance and affects populations from Northern Europe, particularly Scandinavians most frequently. It is due to a deficiency of phytanic acid hydroxylase, an enzyme that breaks down a fatty acid called phytanic acid. This condition affects the nervous system, eyes, bones, and skin. Symptoms, which usually appear by age 20 years, include vision problems (**retinitis pigmentosa** and rhythmic eye movements [nystagmus]), loss of muscle coordination, loss of sense of smell (**anosmia**), pain, numbness, and elevated protein in the cerebrospinal fluid. Later symptoms include deafness, abnormalities with the heartbeat (cardiac arrnythmias), lack of coordination (ataxis), weakness and numbness (peripheral neuropath), and scaly, dry skin (**ichthyosis**). Still other people may have shortened toes or fingers. If symptoms do not appear in the 20s, they may begin appearing in the 40s or 50s.

Treatment

A diet free of phytanic acid (found in dairy products, fatty fish [such as tuna, cod, and haddock], lamb, stewed beef and lamb, white bread, white rice, boiled potatoes, and egg yolk) can reduce some of the symptoms. **Plasmapheresis**, a process where whole blood is removed from the body, processed through a filtering system, and then return to the body, may be used to filter phytanic acid from the blood.

Prognosis

Refsum's disease is the lipidoses that is most treatable because a change in diet can control the disease. By removing phytanic acid from the diet, the symptoms associated with it usually disappear. Problems with hearing, vision, and smell may continue even with treatment. If left untreated, the disease may eventually lead to death from irregularities of the heart.

Tay-Sachs disease

Causes and symptoms

Tay-Sachs disease (TSD) is a fatal condition caused by a deficiency of the enzyme beta-hexosaminidase A, which allows excessive amounts of the fatty material called ganglioside G_{M2} to build up in tissues and nerve cells within the brain. The defective gene that causes this disorder is found in roughly 1 in 250 people in the general population. However, certain populations have significantly higher rates of TSD. French-Canadians living near the St. Lawrence River and in the Cajun regions of Louisiana are at higher risk of having a child with TSD. The highest risk seems to be in people of Eastern European and Russian Jewish (Ashkenazi) descent. Tay-Sachs disease has a recessive pattern of inheritance, and approximately 1 in every 27 people of Jewish ancestry in the United States carries the TSD gene. Symptoms develop in infancy and are due to the accumulation of a fatty acid compound in the nervous system. Early symptoms include reduced vision and physical coordination, deafness, seizures, red spots on retina of

KEY TERMS

Amniocentesis—A procedure where a needle is inserted through the abdomen into the uterus of a pregnant woman to remove a small amount of the fluid that surrounds the developing fetus. This test can be performed at about week 16 of the pregnancy. Cells from the fetus can be tested for genetic defects.

Chorionic villi sampling—A procedure to remove a small tissue sample of the placenta, the sac that surrounds the developing fetus. This test can be performed as early as week 10 of the pregnancy. The tissue can be tested for genetic defects.

Lipids—Organic compounds not soluble in water, but soluble in fat solvents such as alcohol. Lipids are stored in the body as energy reserves and are also important components of cell membranes.

Recessive—Refers to an inherited characteristic or trait that is expressed only when two copies of the gene responsible for it are present.

X-linked—Refers to a gene carried on the X chromosome, one of the two sex chromosomes.

eyes, and ID. Eventually, the child develops problems with breathing and swallowing. Blindness, paralysis, and death follow. In another type of the disease, it occurs in people in their 20s or early 30s. They begin to have problems walking. Eventually, their nervous system progressively deteriorates.

Diagnosis

Carriers of the Tay-Sachs related gene can be identified with a blood test. Amniocentesis or chorionic villi sampling can be used to determine if the fetus has Tay-Sachs disease.

Treatment

Treatment options are not available for Tay-Sachs disease. Parents who are identified as carriers may want to seek **genetic counseling**. If a fetus is identified as having TSD, parents may consider termination of the **pregnancy**. If a person contracts the disease, anticonvulsant medication can be prescribed to control seizures. As neurological problems continue, swallowing may be difficult, and a feeding tube may be inserted to help in providing nutrient.

Prognosis

Children born with Tay-Sachs disease become increasingly debilitated; most die by about age four years, usually from infections.

Wolman's disease

Causes and symptoms

Wolman's disease, a type of acid lipase deficiency and acid lipase disease, is caused by a genetic defect (with a recessive pattern of inheritance) that results in deficiency of an enzyme that breaks down cholesterol. It occurs in both males and females. This causes large amounts of fat to accumulate in body tissues. Infants are born without symptoms and they appear to be normal. However, symptoms begin in the first few weeks of life and include an enlarged liver and spleen, adrenal calcification (hardening of adrenal tissue due to deposits of **calcium** salts), vomiting, anemia, **jaundice**, and fatty stools.

Treatment

Treatment is not currently available.

Prognosis

Infants usually die by the age of one year. They usually die from **malnutrition**. However, if they survive as children, they may live into adulthood

Prevention

Couples who have family histories of genetic defects can undergo genetic testing and counseling to see if they are at risk for having a child with one of the lipidoses disorders. During pregnancy, cell samples can be collected from the fetus using amniocentesis or chorionic villi sampling. The results of these tests can indicate if the developing fetus has a lipidosis disorder. Termination of the pregnancy may be considered in some cases.

Lipoproteins test

Definition

Lipoproteins are the "packages" in which **cholesterol** and **triglycerides** travel throughout the body. Measuring the amount of cholesterol carried by each type of lipoprotein helps determine a person's risk for cardiovascular disease (disease that affects the heart and blood vessels, also called CVD).

Purpose

Cholesterol and triglycerides are fat-like substances called lipids. Cholesterol is used to build cell membranes and hormones. The body makes cholesterol and gets it from food. Triglycerides provide a major source of energy to the body tissues. Both cholesterol and triglycerides are vital to body function, but an excess of either one, especially cholesterol, puts a person at risk of cardiovascular disease.

Because cholesterol and triglycerides can't dissolve in watery liquid, they must be transported by something that can dissolve in blood serum. Lipoproteins contain cholesterol and triglycerides at the core and an outer layer of protein, called apolipoprotein.

There are four major classes of lipoproteins: chylomicrons, very low-density lipoproteins (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL). There also are less commonly measured classes such as lipoprotein(a) and subtypes of the main classes. Each lipoprotein has characteristics that make the cholesterol it carries a greater or lesser risk. Measuring each type of lipoprotein helps determine a person's risk for cardiovascular disease more accurately than cholesterol measurement alone. When a person is discovered to be at risk, treatment by diet or medication can be started and his or her response to treatment monitored by repeated testing.

Description

Chylomicrons

Chylomicrons are made in the intestines from the triglycerides in food. They contain very little cholesterol. Chylomicrons circulate in the blood, getting

smaller as they deposit the triglycerides in fatty tissue. Twelve hours after a meal, they are gone from circulation. Serum collected from a person directly after eating will form a creamy layer on the top if left undisturbed and refrigerated overnight. This creamy layer is the chylomicrons.

Very low-density lipoproteins (VLDL)

VLDL are formed in the liver by the combination of cholesterol, triglycerides formed from circulating fatty acids, and apolipoprotein. This lipoprotein particle is smaller than a chylomicron, and contains less triglyceride but more cholesterol (10–15% of a person's total cholesterol). As the VLDL circulates in the blood, triglycerides are deposited and the particle gets smaller, eventually becoming a low-density lipoprotein (LDL). Serum from a person with a large amount of VLDL will be cloudy.

Low-density lipoproteins (LDL)

LDL, often called "bad" cholesterol, is formed primarily by the breakdown of VLDL. LDL contains little triglycerides and a large amount of cholesterol (60–70% of a person's total cholesterol). Although the particles are much smaller than chylomicrons and VLDL, LDL particles can vary in size and chemical structure. These variations represent subclasses within the LDL class. Serum from a person with a large amount of LDL will be clear.

LDL carries cholesterol in the blood and deposits it in body tissues and in the walls of blood vessels, a condition known as atherosclerosis. The amount of LDL in a person's blood is directly related to his or her risk of cardiovascular disease. The higher the LDL level, the greater the risk. LDL is the lipoprotein class most used to trigger and monitor cholesterol lowering therapy.

High-density lipoproteins (HDL)

HDL is often called "good" cholesterol. HDL removes excess cholesterol from tissues and vessel walls and carries it to the liver, where it is removed from the blood and discarded. The amount of HDL in a person's blood is inversely related to his or her risk of cardiovascular disease. The lower the HDL level, the greater the risk; the higher the level, the lower the risk. The smallest lipoprotein, it contains 20–30% of a person's total cholesterol and can be separated into two major subclasses.

Lipoprotein(a)

Lipoprotein(a) is found in lower concentrations than other lipoproteins, yet it carries a unique and significant risk for cardiovascular disease. Because of its similarity to LDL, test methods often don't measure it separately, but include it within the LDL class. Testing specifically for this class may uncover why a person is not responding to standard cholesterol-lowering treatment. High lipoprotein(a) levels may not respond to treatment aimed at high LDL.

Measurement guidelines

The Expert Panel of the National Cholesterol Education Program (NCEP) sponsored by the National Institutes of Health has published guidelines for the detection of high cholesterol in adults. The NCEP panel recommends that adults over the age of 20 be tested for cholesterol and HDL every five years. If the cholesterol is high, the HDL is low (below 35 mg/dL), or other risk factors are present, a complete lipoprotein profile that includes total cholesterol, triglycerides, HDL, and calculated LDL should be done.

Measurement methods

There are a variety of methods to measure the lipoprotein classes. All require separation of the classes before they can be measured. One way to separate them is by spinning serum (the yellow, watery liquid that separates from the cells when **blood clots**) for a long time in a high-speed centrifuge (called ultracentrifugation). The most dense classes will settle toward the bottom, the least dense toward the top. Following centrifugation, the most complete measurement of all the lipoprotein classes is done using electrophoresis. This procedure measures the quantity of each lipoprotein class based on its movement in an electrical field.

In 2003, a test called the vertical auto profile or VAP, was developed that provides detailed measurements of cholesterol subclasses. These subclasses play important roles in patients later developing **heart disease**. The new tests were predicted to help identify important, emerging risk factors for heart disease.

Other, less extensive procedures also are used. For example, if only HDL is to be measured, a chemical is added to the serum that will clump the other classes, leaving HDL free in the serum to be measured by a chemical method. LDL often is not measured directly but its level is calculated based on the measurements of total cholesterol, HDL, and triglycerides. The formula is called the Friedewald formula: LDL = total cholesterol - HDL - (triglycerides/5). The calculated result will be inaccurate in a person with high triglycerides. Results usually are available the same or following day.

KEY TERMS

Atherosclerosis—Disease of blood vessels caused by deposits of cholesterol on the inside walls of the vessels.

Cardiovascular disease—Disease that affects the heart and blood vessels.

Cholesterol—A fat-like substance called a lipid. It is used to build cell membranes and hormones. The body makes cholesterol and gets it from food.

Lipoproteins—The packages in which cholesterol and triglycerides travel throughout the body.

Preparation

The patient must fast for 12 hours before the test, eating nothing and drinking only water. The person should not have alcohol for 24 hours before the test. There should be a stable diet and no illnesses occurring in the preceding two weeks.

A lipoproteins test requires 5 mL (milliliters) of blood. A person's physical position while having blood collected affects the results. Values from blood drawn while a person is sitting may be different from those while the person is standing. If repeated testing is done, the person should be in the same position each time.

Aftercare

Discomfort or bruising may occur at the puncture site or the person may feel dizzy or faint. Pressure to the puncture site until the bleeding stops reduces bruising. Warm packs to the puncture site relieve discomfort.

Results

People with HDL levels between 45 mg/dL and 59 mg/dL carry an average risk for cardiovascular disease. People with HDL levels above 60 mg/dL have a negative risk factor and appear to be protected from cardiovascular disease.

LDL levels below 130 mg/dL are desirable.

Some people have normal variations in their lipoprotein and total cholesterol levels. Repeat testing may be necessary, especially if a value is at a borderline risk category point.

Abnormal results

People with HDL levels of 36–44 mg/dL have a moderate risk of cardiovascular disease. HDL levels below 35 mg/dL are a major risk.

LDL levels of 130–159 mg/dL place a person at a borderline high risk of cardiovascular disease; levels above 160 mg/dL place a person at high risk. Relative proportions between HDL and LDL are important also. Results of a large clinical trial in 2003 showed that the new VAP cholesterol tests increased lipid-lowering therapy by 59% in high-risk patients with diabetes.

Liposuction

Definition

Liposuction, also known as lipoplasty or suction-assisted lipectomy, is **cosmetic surgery** performed to remove unwanted deposits of fat from under the skin. The surgeon sculpts and re-contours a person's body by removing excess fat deposits that have been resistant to reduction by diet or **exercise**. Removal of fat cells is permanent.

Purpose

Liposuction is intended to reduce and smooth the contours of the body and improve a person's appearance. Its goal is cosmetic improvement. Liposuction

does not remove large quantities of fat and is not intended as a weight-reduction technique. The average amount of fat removed is about 1 quart (1 liter). Although liposuction is not intended to remove cellulite (lumpy fat), some doctors believe that it improves the appearance of areas that contain cellulite, including thighs, hips, buttocks, abdomen, and chin. A technique called liposhaving shows more promise at reducing cellulite. Liposhaving can be done under local **anesthesia** and is reported to be less traumatic to the skin than liposuction. Liposuction is most often performed by board-certified plastic surgeons.

Demographics

According to the American Society of Plastic Surgeons, liposuction is the third most commonly performed cosmetic procedure for both men and women in the United States. In 2012, about 202,128 liposuction procedures were performed in the United States, a decrease of almost 50% from the number performed in 2006.

Description

Many liposuction surgeries are performed by plastic surgeons or by dermatologists. Any licensed physician may legally perform liposuction. Liposuction may be performed in a private professional office, an outpatient center, or in a hospital.

Most liposuction procedures are performed under local anesthesia. Local anesthesia produces loss of sensation without loss of consciousness. The tumescent, or wet, technique is used most often. In this technique, a large volume of very dilute anesthetic is injected under the person's skin, making the tissue swollen (tumescent) and firm. Epinephrine is added to the solution to reduce bleeding, which allows for the removal of larger amounts of fat.

The physician first numbs the skin with an injection of local anesthetic. After the skin is desensitized, the doctor makes a series of tiny incisions no larger than 0.12–0.25 in (3–6 mm) in length. Flooding the area with more dilute anesthetic, fat is then extracted with suction through a long, blunt hollow tube called a cannula. The doctor repeatedly pushes the cannula through the fat layers in a radiating pattern creating tunnels, thus removing fat and re-contouring the area.

Some newer modifications to the procedure include the use of a cutting cannula called a liposhaver. Formerly some surgeons used **ultrasound** to help break up the fat deposits, but this technique has largely been abandoned because it created greater safety risks than the tumescent technique. Larger incisions may be closed with a suture or staple, while micro incisions are covered with bandages but do not need sutures. Incisions usually heal completely within two weeks and should leave few or no **scars**.

The length of time required to perform the procedure varies with the amount of fat that is to be removed and the number of areas to be treated. Most operations take from 30 minutes up to two hours, but extensive procedures can take longer. Risk of complications increases with the extensiveness of the procedure. The length of time required also varies with the manner in which the anesthetic is injected.

The cost of liposuction varies depending upon the fees commonly charged in the region of the country where it is performed, the extent of the area being treated, and the person performing the procedure.

An increasing trend in the twenty-first century is for Americans to go overseas to have cosmetic procedures performed in countries where they cost substantially less than in the United States. These procedures are cosmetic and are not covered by most insurance policies.

Preparation

Liposuction is most successful when performed on persons who have firm, elastic skin and concentrated pockets of fat in areas that are characterized by cellulite. To get good results after fat removal, the skin must contract to conform to the new contours without sagging. Older persons have less elastic skin and, consequently, may not be good candidates for this procedure. People with generalized fat distribution, rather than localized pockets, are not good candidates. Candidates should be in good general health and free of heart or lung disease. People who have poor circulation or who have had recent surgery at the intended site of fat reduction are not good candidates.

KEY TERMS

Cellulite—Dimpled skin that is caused by uneven fat deposits beneath the surface.

Epinephrine—Epinephrine, also called adrenalin, occurs naturally in the body and causes blood vessels to constrict or narrow. As a drug, it is used to reduce bleeding.

Hemoglobin—The component of blood that carries oxygen to the tissues.

Liposhaving—Involves removing fat that lies closer to the surface of the skin by using a needle-like instrument that contains a sharp-edged shaving device.

The doctor will conduct a **physical examination** and may order blood work to determine clotting time and hemoglobin level for transfusions, in case the need should arise. The person may be placed on **antibiotics** before surgery to ward off potential infection.

Aftercare

Liposuction is normally an outpatient procedure. Patients should plan to have someone available to drive them home and stay with them for the next 12–24 hours. If the tumescent technique is used, the patient will feel little or no **pain** for 24 hours following the procedure but after that may have soreness and swelling for several weeks. After some liposuction surgery, the patient may need to wear a support garment continuously for 2–3 weeks. If ankles or calves were treated, support hose should be worn for up to 6 weeks. The support garments can be removed during bathing. A drainage tube placed under the skin in the area of the procedure may be needed to prevent fluid buildup.

The incisions involved in this procedure are tiny, but the surgeon may close them with metal sutures or staples. These will be removed a few days surgery. Some micro-incisions are small enough that the doctor may not need to close them with sutures. Minor bleeding or seepage through the incision site(s) is common after this procedure. Wearing the elastic bandage or support garment helps reduce fluid loss.

The patient usually can return to normal activity within a week. Any postoperative bruising is expected to go away within 10–14 days. Postoperative swelling

begins to go down after a week. It may take 3–6 months for the final contour to be reached depending on the extent of the surgery.

Results

The loss of fat cells is permanent, and the patient should have smoother, more pleasing body contours without excessive bulges. Nevertheless, if the patient overeats, the remaining fat cells will grow in size. Although the patient may gain weight, the body should retain the new proportions and the suctioned area should remain proportionally smaller.

Tiny scars at the site of incision are normal. The doctor usually makes the incisions in places where the scars are not likely to show.

In some instances, the skin may appear rippled, wavy, or baggy after surgery. Pigmentation spots may develop. The re-contoured area may be uneven. This unevenness can be corrected with a second procedure that is less extensive than the first.

Morbidity and mortality rates

The morbidity rate from liposuction is less than 1%. Mortality is exceedingly rare.

Risks

Liposuction under local anesthesia using the tumescent technique is exceptionally safe so long as the patient is in good health. The main hazards associated with this surgery involve migration of a blood clot or fat globule to the heart, brain, or lungs. Such an event can cause a **heart attack** or **stroke**. Ultrasound-assisted liposuction has largely been abandoned because of safety concerns such as **burns** and complications such as scarring.

Staying in bed increases the risk of clot formation, but too much activity can result in increased swelling of the surgical area. Such swelling is a result of excess fluid and blood accumulation, and generally comes from not wearing the compression garments. If necessary, this excess fluid can be drained with a needle in the doctor's office.

Infection is another complication, but this rarely occurs. If the physician is skilled and works in a sterile environment, infection should not be much of a concern.

The greatest risk of complications arises when too much fat is removed or too many parts of the body are worked on at one time. If too much fat is removed, the skin may peel in that area. Smokers are at increased risk for shedding skin because their circulation is impaired. Removing too much fat may also cause the patient to go into **shock**.

Alternatives

Some of the alternatives to liposuction include modifying diet to lose excess body fat, exercising, learning to accept the body and appearance as it is, or using clothing or makeup to downplay or emphasize body or facial features.

Listeria infections

Definition

Listeria infections, commonly called **listeriosis**, are bacterial illnesses caused by *Listeria monocytogenes* and five other *Listeria* species; however, most infections in humans are caused by *L. monocytogenes*. The bacterium is responsible for various infections of the central nervous system; **bacteremia** in people with weakened immune systems; and **gastritis** in healthy persons who have eaten food contaminated with the bacterium. *Listeria* infections in which the bacterium penetrates the digestive tract to cause systemic infection are called invasive listeriosis. While uncommon in the general population, these invasive infections are potentially fatal to susceptible individuals.

L. monocytogenes usually enters the human body through vegetables, meat from infected animals, unpasteurized milk, or soft cheeses and other processed foods contaminated after processing; however, about 10% of humans carry *Listeria* in their digestive tracts without having any symptoms of illness. The bacterium can infect sheep, cattle, rabbits, mice, and other animals as well as humans; it has been detected in 42 species of domesticated and wild animals as well as 22 species of birds. In fact, veterinarians are more likely than practitioners of human medicine to recognize cases of listeriosis because it is a frequent cause of encephalitis and late-term miscarriages in farm animals. Because *Listeria* can be transmitted from other animals to humans, it is classified as a **zoonosis** or zoonotic disease. The Centers for Disease Control and Prevention (CDC) added invasive listeriosis to its list of notifiable diseases in 2001.

Description

All *Listeria* species are gram-positive anaerobic coccobacilli that are highly resistant to heat and cold. The genus is named for Joseph Lister (1827–1912), an eminent British surgeon who pioneered antisepsis in surgery. *Listeria* bacteria can grow in a wide temperature range, from 39°F to 111°F, which means that they can multiply in inadequately refrigerated foods as well as foods at room temperature. *Listeria* species are ubiquitous in the natural environment; they can be found in water, silage, soil, fecal matter, and sewage; the natural reservoirs of the organisms, however, appear to be soil and the digestive tracts of animals, which serves to explain why vegetables grown in soil fertilized with manure are frequently contaminated with the bacterium.

(Elizabeth White/Centers for Disease Control and Prevention)

There are several different types of *Listeria* infections, ranging from self-limited infections of the skin to potentially deadly invasive infections of the central nervous system. The symptoms vary according to the location of the infection in the patient's body, and are described more fully below.

Risk factors

Risk factors for listeriosis include the following:

- Pregnancy: pregnant women are 10 times more likely than adults in the general population to develop listeriosis.
- Age: older adults and newborn infants are more susceptible to *Listeria* infections than people in other age groups. In older adults, the risk rises sharply after age 50; the average age of patients in the 2011 outbreak described in the next section was 77.
- Occupation: farmers, gardeners, veterinarians, and others who work with farm animals are at greater risk of listeriosis.
- Concurrent illnesses: People with AIDS, cancer patients, patients taking corticosteroid medications, alcoholics, persons with type 1 diabetes or liver disease, and others with weakened immune systems are at high risk of *Listeria* infections.
- Cultural preferences in food. Pregnant Hispanic women have 24 times the risk of listeriosis than people in the general US population because of their preference for Mexican-style cheese.

Demographics

L. monocytogenes is a common organism found worldwide, although outbreaks of listeriosis are more common in countries in the temperate climate zones than in the tropics. Noninvasive gastritis caused by *L. monocytogenes* is fairly common in otherwise healthy adults and is usually not traced to a specific species of *Listeria* because the **diarrhea** and other symptoms go away in a few days. It is the invasive form of listeriosis that concerns **public health** officials. According to the CDC, there are on average 9.7 cases of invasive listeriosis per million in the United States, or about 1600 per year; 27% of these cases occur in pregnant women. The mortality rate of invasive listeriosis is 20–30%; on average, 260 Americans die each year of invasive listeriosis. *L. monocytogenes* is the third most deadly foodborne disease organism in North America.

There have been two notable outbreaks of invasive listeriosis in North America since 2008, one in Canada and one in the United States. The 2008 Canadian outbreak was traced to a food processing plant in Toronto, Ontario, and led to 57 confirmed cases and 23 deaths. The 2011 outbreak in the United States was traced to contaminated cantaloupes grown on a farm in Colorado. Between August and September 2011, 147 cases of invasive listeriosis from 28 states were reported to the CDC; 33 patients died, and one pregnant woman suffered a **miscarriage**. This was the most severe outbreak in the United States since 1924.

Causes and symptoms

The cause of listeriosis in humans is infection with *L. monocytogenes*, most commonly as a result of ingesting contaminated food or water. There have been cases, however, of farmers or others who work with animals developing skin infections from handling animal fetuses aborted as a result of listeriosis.

Symptoms of listeriosis vary depending on whether the person has a simple case of **food poisoning** from eating food contaminated by *L. monocytogenes*; has developed a skin infection caused by the bacterium; or has the invasive form of the disease:

- People with noninvasive gastritis caused by *L. monocytogenes* typically experience from 1 to 3 days of diarrhea with fever, muscle aches, nausea, and

WWW.BOOKBAZ.IR

headaches. It can take *L. monocytogenes* as long as 21 days to incubate in the digestive tract and cause the symptoms of food poisoning, although the usual incubation period is 1 to 2 days.

- Neonatal infection with *L. monocytogenes* occurs either during pregnancy or during vaginal delivery of the newborn. Infection before birth results in premature birth, with *L. monocytogenes* being found in the placenta and in the infant's blood, nose, ears, and throat. Infection acquired during vaginal delivery usually results in meningitis, or infection of the membranes covering the infant's brain. This complication is potentially fatal.
- Listeriosis in pregnant women usually occurs in the third trimester of pregnancy and consists of flu-like symptoms (fever, muscle and joint pains, and headaches) lasting from 7 to 10 days. The real risk is to the unborn child, as listeriosis in pregnant women can result in miscarriage, stillbirth, or premature birth.
- Cutaneous listeriosis is an infection of the skin that develops in farmers, veterinarians, and others who may handle the stillborn or aborted offspring of infected sheep or goats without protecting their hands with birthing gloves. On rare occasions gardeners have developed cutaneous listeriosis from working with plants in contaminated soil. Cutaneous listeriosis may take the form of a rash on the surface of the skin or an infection of the joints known as septic arthritis. The rash is usually not painful or itching and is self-limited, although some patients also have a low-grade fever.
- Invasive listeriosis, the most dangerous form of the infection, results from the presence of *L. monocytogenes* in the tissues of the central nervous system (CNS). The organism is particularly likely to infect the brain stem and the meninges. Symptoms include changes in mental status, seizures (in 25% of patients), tremor, loss of balance and muscular coordination, partial paralysis, headache and neck stiffness, high fever, vomiting, and deficits in the cranial nerves. About 10% of CNS infections result in abscesses; this complication of invasive listeriosis has a high mortality rate. A few cases of invasive listeriosis involve the tissues of the heart, with the bacteria forming small colonies in the heart tissue (endocarditis).

Diagnosis

People with the symptoms of invasive listeriosis—particularly if they belong to a high-risk group—should see their doctor at once. The diagnosis of any form of listeriosis is confirmed only after *L. monocytogenes* has been isolated from blood, spinal fluid (in cases of CNS involvement) or amniotic fluid (in cases of **pregnancy**). It takes one or two days for the organism to be cultured in the laboratory. There are no reliable stool tests for *L. monocytogenes*.

Treatment

Cutaneous and noninvasive gastrointestinal listeriosis usually clear up without antibiotic therapy, although patients with gastritis may require supportive treatment for the diarrhea and nausea.

Invasive listeriosis affecting the central nervous system is treated with intravenous **antibiotics**, usually ampicillin (Omnipen) with the possible addition of gentamicin. Patients who cannot take ampicillin may be treated with trimethoprim-sulfamethoxazole (Bactrim). **Meningitis** should be treated for 3 weeks; **endocarditis** for 4–6 weeks; and brain abscesses for at least 6 weeks. Pregnant women diagnosed with listeriosis can be given antibiotics to prevent infection of the unborn child, and newborns can be treated with the same antibiotics as adults.

Prognosis

The prognosis depends on whether the infection is invasive or noninvasive; the patient's general health; and promptness of treatment in cases of invasive listeriosis.

Prevention

Prevention of *Listeria* infections depends on proper storage and preparation of foods, and avoidance of raw milk and foods made from unpasteurized milk. Specific recommendations include:

- Cleaning of raw fruits and vegetables under running tap water before peeling or eating; scrubbing firm vegetables (carrots, cucumbers, etc.) with a clean produce brush; and storing produce and ready-to-eat foods away from uncooked meat or poultry.
- Setting the refrigerator temperature to 40°F or lower and the freezer temperature to 0°F or lower.
- Throwing out all food past its use-by date. Hot dogs should be kept no longer than 7 days after opening the package; sliced meats from the deli, no longer than 3 to 5 days. Juices from raw meat, opened luncheon meats, or other food spills in the refrigerator should be cleaned up promptly with soap and water.
- Washing hands and all cutting boards, knives, and countertops after handling and preparing uncooked foods.
- People at increased risk of invasive listeriosis should avoid the following foods: hot dogs (unless heated to a temperature of 165°F and steaming hot), luncheon

KEY TERMS

Anaerobic—Able to live in the absence of oxygen.

Bacteremia—The presence of bacteria in the bloodstream.

Coccobacillus (plural, ccoccobacilli)—A short rod-shaped bacterium. *Listeria* species are coccobacilli.

Cutaneous—Pertaining to the skin.

Endocarditis—Inflammation of the inner layer of heart tissue. It may be either infective (caused by a microorganism) or noninfective.

Notifiable disease—Any disease that is required by law to be reported to public health authorities. In the United States, the CDC maintains a list of nationally notifiable diseases monitored by the National Notifiable Diseases Surveillance System (NNDSS). Listeriosis was added to the list in 2001.

Zoonosis (plural, zoonoses)—Any disease that can be transmitted from other animals to humans, or from humans to other animals.

meats, and deli meats; salads made in a store (macaroni and potato salads, tuna or seafood salads, etc.); soft cheeses (feta, queso blanco, queso fresco, brie, Camembert, blue-veined, or panela) unless they are clearly labeled as made with pasteurized milk; and refrigerated smoked fish or meat spreads. Shelf-stable canned meat spreads or canned tuna and salmon are safe to eat.

Listeriosis

Definition

Listeriosis is an **infectious disease** caused by a bacterium, *Listeria monocytogenes*, which is most commonly acquired by eating contaminated food.

WWW.BOOKBAZ.IR

The organism can spread to the blood stream and central nervous system. During **pregnancy**, listeriosis often causes **miscarriage** or **stillbirth**. It is also more likely to cause serious illness in the elderly, in newborns, or in people with weakened immune systems. Although listeriosis is infectious (caused by a disease organism), it is not contagious; that is, it is not spread by direct contact with other infected persons, with the exception of vaginal transmission during **childbirth**.

Demographics

Listeriosis, also called listeria infection, is usually an uncommon disease in the general human population in North America and Western Europe. There are on average 9.7 cases per million persons per year in Canada and the United States, and five cases per million per year in Europe; however, European doctors have reported as of 2014 that the rate of listeriosis in Europe has been rising since 2005. Listeriosis is far more common among domestic animals, farm animals (particularly cattle and sheep), game animals, poultry, and wild birds than among humans. Listeriosis outbreaks are sporadic (rare and scattered in occurrence) rather than epidemic; they are, however, more common in cold or temperate climates than in the tropics, and more likely to occur in the summer in North America. The most recent foodborne outbreak in the United States occurred in Massachusetts in 2007 and involved contaminated milk.

Description

Listeriosis is caused by an infection with the gram-positive bacterium *Listeria monocytogenes*. The bacterium was named for Joseph Lister (1827–1912), a British surgeon honored as the pioneer of antiseptic surgery. The bacterium is rod-shaped and moves about with the help of a small flagellum. It secretes a chemical that causes the destruction of red blood cells.

This bacterium is carried by at least 64 different species of animals, and it has also been found in soil, water, sewage, and animal feed. Five out of every 100 people carry *L. monocytogenes* in their intestines. The bacterium is hardy and can survive in a wide temperature range, from 39°F (3.9°C) to 111°F (43.9°C). It is found almost everywhere in the world in plants and soils.

Listeriosis is considered a foodborne disease because most people become infected after eating food contaminated with *L. monocytogenes*. However, a woman can pass the bacteria to her baby during pregnancy. In addition, there have been a few cases in which veterinarians or farm workers have developed *Listeria* skin infections by touching infected calves or poultry.

There are five distinct clinical forms of listeriosis:

- Infection during pregnancy, most commonly in the third trimester.
- Neonatal (newborn) infection, which can take two forms: an early-onset inflammation of the entire body (sepsis), which usually results in premature birth; and a late-onset infection of the central nervous system, which the baby acquires during vaginal delivery.
- Central nervous system (CNS) infection. *L. monocytogenes* has a special predilection for the central nervous system of humans. The infection may take the form of inflammation of the membranes covering the brain (meningitis), paralysis of the cranial nerves, inflammation of the brain tissue itself (encephalitis), or abscesses. Patients may suffer from seizures and changes in mental status.
- Gastroenteritis (inflammation of the digestive tract). *L. monocytogenes* can cause diarrhea lasting one to three days.
- Cutaneous listeriosis. This is an infection of the skin most likely to affect veterinarians and others who handle infected farm or wild animals.

Risk factors

Persons at particular risk for listeriosis include the elderly, pregnant women, newborns, those who take glucocorticosteroid medications (which suppress immune responses to infection), and those with a weakened immune system (immunocompromised). Risk is increased when a person suffers from diseases such as **AIDS**, cancer, **kidney disease**, **diabetes mellitus**, or by the use of certain medications. Infection is most common in babies younger than one month old and adults over 60 years of age. Pregnant women account for 27% of the cases and immunocompromised persons account for almost 70%. Persons with AIDS are 280 times more likely to get listeriosis than others.

With the exception of pregnant women, sex is not a risk factor for listeriosis; neither is race nor ethnicity.

Causes and symptoms

As noted, persons become infected with *L. monocytogenes* by eating contaminated food. *Listeria* has been found on raw vegetables, fish, poultry, raw (unpasteurized) milk, fresh meat, processed meat (such as deli meat, hot dogs, and canned meat), and certain soft cheeses—particularly Brie, Camembert,

feta cheese, and bleu cheese. Listeriosis outbreaks in the United States since the 1980s have been linked to cole slaw, milk, Mexican–style cheese, undercooked hot dogs, undercooked chicken, and delicatessen or salad bar–type foods.

Unlike most other bacteria, *L. monocytogenes* does not stop growing when food is in the refrigerator—its growth is merely slowed. Although initial levels of the bacterium in contaminated foods are usually low, its ability to survive and multiply at low temperatures allows it to reach levels high enough to cause human disease, particularly if contaminated foods that allow for the growth of the organism are stored for prolonged times under refrigeration. Fortunately, typical cooking temperatures and the pasteurization process in milk do kill this bacterium.

Listeria bacteria can pass through the wall of the intestines, and from there they can get into the blood stream. Once in the blood stream, they can be transported anywhere in the body, but are commonly found the central nervous system (brain and spinal cord). In pregnant women they are often found in the placenta (the organ which connects the baby's umbilical cord to the uterus). *Listeria monocytogenes* live inside specific white blood cells called macrophages. Inside macrophages, the bacteria can hide from immune responses and become inaccessible to certain **antibiotics**. *Listeria* bacteria are capable of multiplying within macrophages, and then may spread to other macrophages.

Gastrointestinal listeriosis

After consuming food contaminated with this bacteria, symptoms of infection may appear anywhere from 11–70 days later. Most people do not get any noticeable symptoms. Scientists are unsure, but they believe that *L. monocytogenes* can cause upset stomach and intestinal problems just like other food-borne illnesses. Persons with listeriosis may develop such flu-like symptoms as **fever**, **headache**, **nausea and vomiting**, tiredness, and **diarrhea**.

Listeriosis in pregnancy

Pregnant women experience a mild, flu–like illness with fever, muscle aches, upset stomach, and intestinal problems. They recover, but the infection can cause miscarriage, **premature labor**, early rupture of the birth sac, and stillbirth. Unfortunately, half of the newborns infected with *Listeria* will die from the illness.

Neonatal listeriosis

There are two types of listeriosis in the newborn baby: early-onset disease and late-onset disease. Early-onset disease refers to a serious illness that is present at birth and usually causes the baby to be born prematurely. Babies infected during pregnancy usually have a blood infection (**sepsis**) and may have a serious, whole body infection called granulomatosis infantisepticum. When a full-term baby becomes infected with *Listeria* during childbirth, that situation is called late-onset disease. Commonly, symptoms of late–onset listeriosis appear about two weeks after birth. Babies with late-term disease typically have **meningitis** (inflammation of the brain and spinal tissues); yet they have a better chance of surviving than those with early-onset disease.

Central nervous system involvement

Immunocompromised adults are at risk for a serious infection of the blood stream and central nervous system (brain and spinal cord). Meningitis occurs in about half of the cases of adult listeriosis. Symptoms of listerial meningitis occur about four days after the flu-like symptoms and include fever, personality change, uncoordinated muscle movement, **tremors**, muscle contractions, seizures, and slipping in and out of consciousness.

L. monocytogenes causes **endocarditis** in about 7.5% of cases of listeriosis. Endocarditis is an inflammation of heart tissue due to bacterial infection. Listerial endocarditis causes death in about half of patients. Other diseases which have been caused by *Listeria monocytogenes* include **brain abscess**, eye infection, hepatitis (**liver disease**), **peritonitis** (abdominal infection), lung infection, joint infection, arthritis, **heart disease**, bone infection, and gallbladder infection.

Diagnosis

Listeriosis may be diagnosed and treated by infectious disease specialists and internal medicine specialists. The diagnosis and treatment of this infection should be covered by most insurance providers.

Examination

The doctor may or may not suspect listeriosis on the basis of an office examination, as the symptoms of a gastrointestinal listeria infection are not unique to *L. monocytogenes*. A patient with listerial meningitis or encephalitis may have seizures, problems with movement, or mental status changes. But again, these can be caused by other disease organisms affecting the CNS. Laboratory tests are required to rule out other causes of the patient's symptoms.

KEY TERMS

Abscess—An accumulation of pus caused by localized infection in tissues or organs. *L. monocytogenes* can cause abscesses in many organs, including the brain, spleen, and liver.

Brain stem—The posterior portion of the brain that connects directly to the spinal cord. It regulates breathing, heart function, and the sleep-wake cycle as well as maintaining consciousness.

Cutaneous—Pertaining to the skin.

Encephalitis—Acute inflammation of brain tissue.

Endocarditis—Inflammation of the endocardium, the inner layer of heart tissue.

Flagellum—A tail-like projection extending from the cell walls of certain bacteria. Its name is the Latin word for "whip."

Glucocorticosteroids—Also called glucocorticoids, a class of steroid hormones that play important roles in metabolism and the immune system. Synthetic glucocorticosteroids are drugs given to control certain allergic and immune system disorders; they include cortisone, prednisone, aldosterone, and dexamethasone. These drugs suppress the immune response to infection; thus they can increase a person's risk of listeriosis.

Immunocompromised—To have a poor immune system due to disease or medication. Immunocompromised persons are at risk for developing infections because they can not fight off microorganisms as can healthy persons.

Macrophages—White blood cells whose job is to destroy invading microorganisms. *Listeria monocytogenes* avoids being killed and can multiply within the macrophage.

Meningitis—Inflammation of the meninges, the layers of membranes that cover and protect the brain and spinal cord.

Sepsis—An inflammatory response of the whole body to an infection. Listeriosis in newborns may take the form of sepsis.

Sporadic—Rare and occasional in occurrence. Listeriosis in humans is a sporadic disease.

Tests

The only way to confirm a diagnosis of listeriosis as of 2014 is to isolate *L. monocytogenes* from blood, cerebrospinal fluid (CSF), urine, or stool. A sample of cerebrospinal fluid is removed from the spinal cord using a needle and syringe. This procedure is commonly called a spinal tap. The amniotic fluid (the fluid that surrounds the unborn baby inside the uterus) may be tested in pregnant women with listeriosis. This sample is obtained by inserting a needle through the abdomen into the uterus and withdrawing fluid. *L. monocytogenes* grows well in laboratory media, and test results can be available within a few days. Blood cultures and CSF tests are more reliable for identifying *L. monocytogenes* than stool tests.

Imaging tests may be performed if endocarditis or involvement of the brain stem are suspect. **Transesophageal echocardiography** is used to diagnose endocarditis. MRI is the most accurate form of imaging for identifying **listeria infections** in the brain stem.

Treatment

Traditional

Medications are the treatment of choice for listeriosis. Intravenous antibiotics must be started immediately as soon as the diagnosis is suspected or confirmed.

Drugs

Listeriosis is treated with antibiotics, most often ampicillin (Omnipen), chloramphenicol (Chloromycetin), or sulfamethoxazole-trimethoprim (Bactrim, Septra). Because the bacteria live within macrophage cells, treatment may be difficult and the treatment periods may vary. Usually, pregnant women are treated for two weeks; newborns, two to three weeks; adults with mild disease, two to four weeks; persons with meningitis, three weeks; persons with brain abscesses, six weeks; and persons with endocarditis, four to six weeks.

Patients are often hospitalized for treatment and monitoring. However, it is not necessary to isolate them because listeriosis is not spread by human contact. Other drugs may be provided to relieve **pain** and fever and to treat other reactions to the infection.

Prognosis

Although listeriosis is a relatively uncommon infectious disease, it does cause significant mortality; the overall mortality rate for listeria infections in humans in 20–30%. Listeriosis is the most virulent form of foodborne disease in North America, with fatality rates higher than those of **botulism** or *Salmonella*food **poisoning**. According to the Centers for Disease Control and Prevention (CDC), there are on average 500 deaths from listeriosis each year in the United States.

Prevention

The CDC recommends the following precautions to prevent getting listeriosis:

- Cook all raw food thoroughly, and wash all raw vegetables carefully.
- Wash hands, knives, and cutting boards in hot soapy water after handling uncooked foods.
- Avoid drinking raw (unpasteurized) milk or consuming dairy products made from raw milk.
- Pregnant women or immunocompromised people should avoid Brie, Camembert, feta, Mexican queso blanco or queso fresco, and bleu cheese. Cream cheese, yogurt, and cottage cheese are safe to eat.
- Reheat leftovers or ready-to-eat foods like hot dogs until they are steaming hot.
- Avoid delicatessen foods unless they can be thoroughly reheated.
- Cook all fish and meat to safe internal temperatures.

Lithotripsy

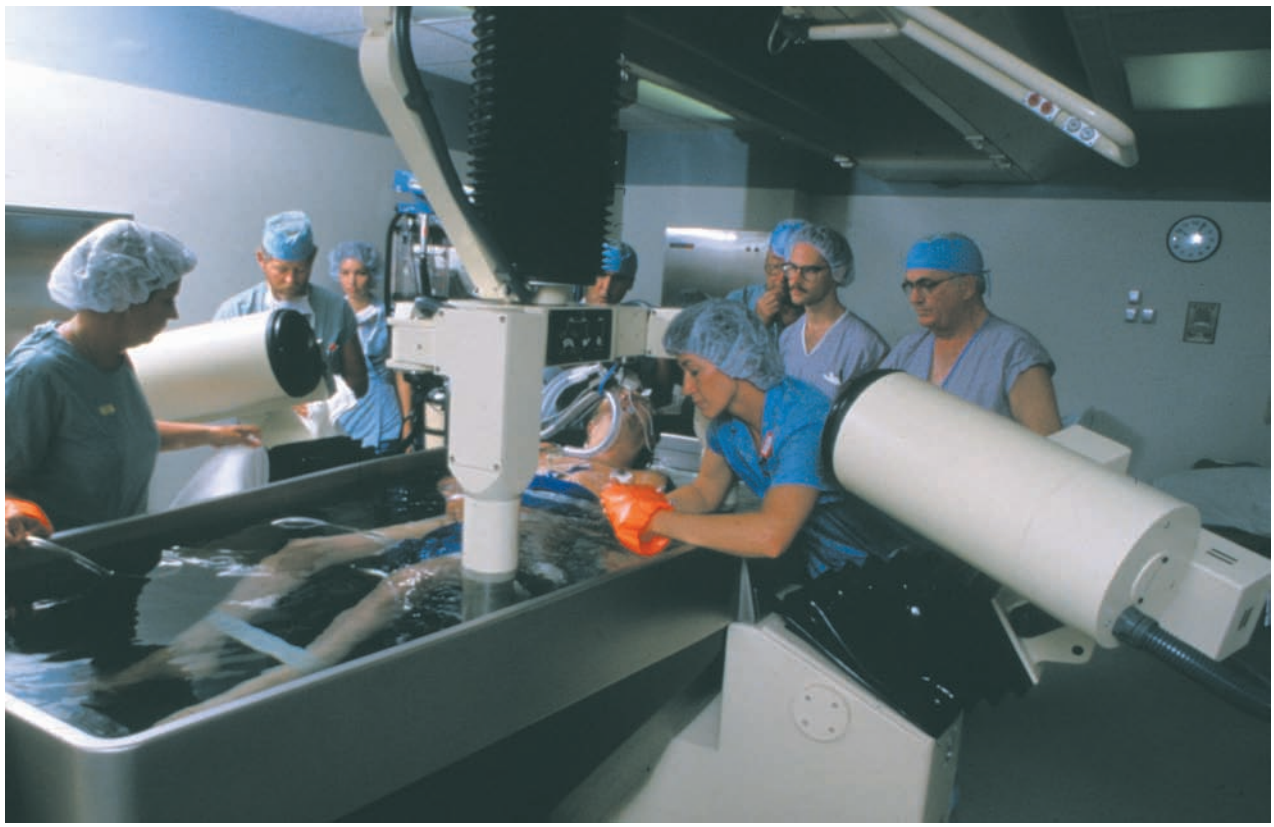
Definition

Lithotripsy is the use of high-energy shock waves to fragment and disintegrate **kidney stones**. The shock wave, created by using a high-voltage spark or an electromagnetic impulse outside of the body, is focused on the stone. The shock wave shatters the stone, allowing the fragments to pass through the urinary system. Since the shock wave is generated outside the body, the procedure is termed extracorporeal shock wave lithotripsy (ESWL). The name is derived from the roots of two Greek words—*litho*, meaning stone, and *trip*, meaning to break.

Purpose

ESWL is used when a kidney stone is too large to pass on its own, or when a stone becomes stuck in a

WWW.BOOKBAZ.IR



A lithotripter in use by patient in tub. This noninvasive method crushes kidney stones through shock waves.
(Photo Researchers, Inc.)

ureter (a tube that carries urine from the kidney to the bladder) and will not pass. Kidney stones are extremely painful and can cause serious medical complications if not removed.

Demographics

For an unknown reason, the number of persons in the United States developing kidney stones has been increasing over the past 20 years. White people are more prone to develop kidney stones than other races. Although stones occur more frequently in men, the number of women who develop them has been increasing over the past 10 years, causing the ratio to change. Kidney stones strike most people between the ages of 20 and 40. Once persons develop more than one stone, they are more likely to develop others. Lithotripsy is not required for treatment in all cases of kidney stones.

Description

Lithotripsy uses the technique of focused shock waves to fragment a stone in the kidney or the ureter. The affected person is placed in contact with a water-filled cushion (older machines require that the individual is actually seated in a tub of water). A sophisticated machine called Lithotripter produces the focused shock waves. A high-voltage electrical discharge is passed through a spark gap under water. The shock waves are focused on the stone inside the person's body. The shock waves are created and focused with the help of a machine called a C-Arm Image Intensifier. The wave shatters and fragments the stone. The resulting debris, called gravel, can then pass through the remainder of the ureter, through the bladder, and through the urethra during urination. There is minimal chance of damage to skin or internal organs because biologic tissues are resilient, not brittle, and because the shock waves are not focused on them.

The shock wave is characterized by a very rapid pressure increase in the transmission medium and is quite different from **ultrasound**. The shock waves are transmitted through a person's skin and pass harmlessly through soft tissues. The shock wave passes through the kidney and strikes the stone. At the edge of the stone, energy is transferred into the stone,

causing small cracks to form on the edge of the stone. The same effect occurs when the shock wave exits the stone. With successive shock waves, the cracks open up. As more cracks form, the size of the stone is reduced. Eventually, the stone is reduced to small particles, which are then flushed out of the kidneys or ureter naturally during urination.

Precautions

ESWL should not be considered for persons with severe skeletal deformities, people weighing more than 300 lb (136 kg), individuals with abdominal aortic aneurysms, or persons with uncontrollable bleeding disorders. Women who are pregnant should not be treated with ESWL. Individuals with cardiac **pacemakers** should be evaluated by a cardiologist familiar with ESWL. The cardiologist should be present during the ESWL procedure in the event the pacemaker needs to be overridden.

Preparation

Prior to the lithotripsy procedure, a complete **physical examination** is performed, followed by tests to determine the number, location, and size of the stone or stones. A test called an intravenous pyelogram (IVP) is used to locate the stones, which involves injecting a dye into a vein in the arm. This dye, which shows up on x-ray, travels through the bloodstream and is excreted by the kidneys. The dye then flows down the ureters and into the bladder. The dye surrounds the stones. In this manner, x-rays are used to evaluate the stones and the anatomy of the urinary system. Blood tests are performed to determine if any potential bleeding problems exist. For women of childbearing age, a **pregnancy** test is done to make sure they are not pregnant. Older persons have an EKG test to make sure that no potential heart problems exist. Some individuals may have a stent placed prior to the lithotripsy procedure. A stent is a plastic tube placed in the ureter that allows the passage of gravel and urine out of the body after the ESWL procedure is completed.

The process of lithotripsy generally takes about one hour. During that time, up to 8,000 individual shock waves are administered. Depending on a person's **pain** tolerance, there may be some discomfort during the treatment. **Analgesics** may be administered to relieve this pain.

Aftercare

Most persons pass blood in their urine after the ESWL procedure. This is normal and should clear after several days to a week. Lots of fluids should be taken to encourage the flushing of any gravel remaining in the urinary system. Treated persons should follow up with a urologist in about two weeks to make sure that everything is progressing as planned. If a stent has been inserted, it is normally removed at this time.

KEY TERMS

Aneurysm—A dilation of the wall of an artery that causes a weak area prone to rupture.

Bladder—Organ in which urine is stored prior to urination.

Bleeding disorder—A problem related to the clotting mechanism of the blood.

Cardiologist—A physician who specializes in problems of the heart.

EKG—A graphical tracing of the electrical activity of the heart.

Extracorporeal shock wave lithotripsy (ESWL)—The use of focused shock waves, generated outside the body, to fragment kidney stones.

Gravel—The debris that is formed from a fragmented kidney stone.

Intravenous pyelogram (IVP)—A type of x-ray. After obtaining an x-ray of the lower abdomen, a radiopaque dye is injected into the veins. X-rays are then obtained every 15 minutes for the next hour. The dye pinpoints the location of kidney stones. It is also used to determine the anatomy of the urinary system.

Kidney stone—A hard mass that forms in the urinary tract that can cause pain, bleeding, obstruction, and/or infection. Stones are primarily composed of calcium.

Stent—A plastic tube placed in the ureter prior to the ESWL procedure, which facilitates the passage of gravel and urine.

Ultrasound—A diagnostic imaging modality that uses sound waves to determine internal structures of the body.

Ureter—A tube that carries urine from the kidney to the bladder.

Urethra—A tube that carries urine from the bladder to the outside of the body.

Urologist—A physician who specializes in problems of the urinary system.

WWW.BOOKBAZ.IR

Results

In most cases, stones are reduced to gravel and passed within a few days. Individuals may return to work whenever they feel able.

Colicky renal pain is very common when gravel is being passed. Other problems may include perirenal hematomas (**blood clots** near the kidneys) in 66% of the cases, nerve palsies, **pancreatitis** (inflammation of the pancreas), and obstruction by stone fragments. Death is extremely rare and usually due to an undiagnosed associated or underlying condition that is aggravated by the lithotripsy procedure.

Risks

Abdominal pain is fairly common after ESWL, but it is usually not a cause for worry. However, persistent or severe abdominal pain may imply an unexpected internal injury. Occasionally, stones may not be completely fragmented during the first ESWL treatment and further lithotripsy procedures may be required.

Some people are allergic to the dye material used during an IVP, so it cannot be used. For these people, focused sound waves, called ultrasound, can be used to identify where the stones are located.

Alternatives

Before the advent of lithotripsy, surgery was used to remove kidney stones. This approach is uncommon today, but occasionally used when other conditions prevent the use of lithotripsy. Attempts are occasionally made to change the pH of urine so as to dissolve kidney stones. This treatment has limited success.

Health care team roles

Lithotripsy is performed by a technician or other individual with specialized training under the supervision of a physician. The physician in charge usually has specialized training in urology. Lithotripsy is most often performed as an outpatient procedure in a facility affiliated with a hospital.

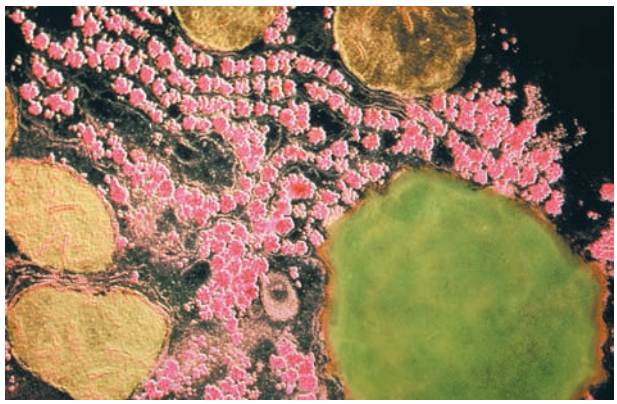
Liver biopsy

Definition

A liver biopsy is a medical procedure performed to obtain a small piece of liver tissue for diagnostic testing. The sample is examined under a microscope by a pathologist, a doctor who specializes in the effects of disease on body tissues—in this case, to detect abnormalities of the liver. Liver biopsies are sometimes called percutaneous liver biopsies, because the tissue



A false color image of hepatocyte cells of the liver that secrete bile. *(Custom Medical Stock Photo, Inc.)*

sample is obtained by going through the patient's skin. This is a useful diagnostic procedure with very low risk and little discomfort to the patient.

Purpose

A liver biopsy is usually done to evaluate the extent of damage that has occurred to the liver because of chronic and acute disease processes or toxic injury. Biopsies are often performed to identify abnormalities in liver tissues after other techniques have failed to yield clear results. In patients with chronic **hepatitis C**, liver biopsy may be used to assess the patient's prognosis and the likelihood of responding to antiviral treatment.

A liver biopsy may be ordered to diagnose or stage any of the following conditions or disorders:

- jaundice
- cirrhosis
- repeated abnormal results from liver function tests
- alcoholic liver disease
- unexplained swelling or enlargement of the liver (hepatomegaly)
- suspected drug-related liver damage such as acetaminophen poisoning
- hemochromatosis, a condition of excess iron in the liver
- intrahepatic cholestasis, the buildup of bile in the liver
- hepatitis
- primary cancers of the liver such as hepatomas, cholangiocarcinomas, and angiosarcomas
- metastatic cancers of the liver (more than 20 times as common in the United States as primary cancers)
- post-liver transplant to measure graft rejection
- fever of unknown origin
- suspected tuberculosis, sarcoidosis, or amyloidosis
- genetic disorders such as Wilson's disease (a disorder in which copper accumulates in the liver, brain, kidneys, and corneas)

Demographics

According to the American Liver Foundation, **liver disease** affects approximately 25 million (1 in 10) Americans annually. **Cirrhosis** accounts for over 27,000 deaths each year. Liver disease is the third most common cause of death among individuals between the ages of 25 and 59, and the seventh most common cause of all disease-related deaths.

Description

Percutaneous liver biopsy is sometimes called aspiration biopsy or fine-needle aspiration (FNA) because it is done with a hollow needle attached to a suction syringe. The special needles used to perform a liver biopsy are called Menghini or Jamshedi needles. The amount of specimen collected should be about 0.03–0.7 fl oz (1–2 cc). In many cases, the biopsy is done by a radiologist, doctor who specializes in x-rays and imaging studies. The radiologist will use computed tomography (CT) scan or **ultrasound** to guide the needle to the target site for the biopsy. Some ultrasound-guided biopsies are performed using a biopsy gun that has a spring mechanism that contains a cutting sheath. This type of procedure gives a greater yield of tissue.

An hour or so before the biopsy, the patient will be given a sedative to aid in relaxation. The patient is then asked to lie on the back with the right elbow to the side and the right hand under the head. The patient is instructed to lie as still as possible during the procedure. He or she is warned to expect a sensation resembling a pinch in the right shoulder when the needle passes a certain nerve (the phrenic nerve), but to remain motionless in spite of the momentary **pain**.

The doctor will then mark a spot on the skin of the abdomen where the needle will be inserted. The right side of the upper abdomen is thoroughly cleansed with an antiseptic solution, generally iodine. The patient is then given a local anesthetic at the biopsy site.

The doctor prepares the needle by drawing sterile saline solution into a syringe. The syringe is then attached to the biopsy needle, which is inserted into

KEY TERMS

Aspiration—The technique of removing a tissue sample for biopsy through a hollow needle attached to a suction syringe.

Bile—Liquid produced by the liver that is excreted into the intestine to aid in the digestion of fats.

Biliary—Relating to bile.

Biopsy—The surgical removal and microscopic examination of living tissue for diagnostic purposes.

Cholestasis—A blockage in the flow of bile.

Cirrhosis—A progressive disease of the liver characterized by the death of liver cells and their replacement with fibrous tissue.

Formalin—A clear solution of diluted formaldehyde that is used to preserve liver biopsy specimens until they can be examined in the laboratory.

Hepatitis—Inflammation of the liver, caused by infection or toxic injury.

Jaundice—Also termed icterus; an increase in blood bile pigments that are deposited in the skin, eyes, deeper tissue, and excretions. The skin and whites of the eyes will appear yellow.

Menghini needle/Jamshedi needle—Special needles used to obtain a sample of liver tissue by aspiration.

Metastatic cancer—A cancer that has been transmitted through the body from a primary cancer site.

Percutaneous biopsy—A biopsy in which the needle is inserted and the sample removed through the skin.

Prothrombin test—A common test to measure the amount of time it takes for a patient's blood to clot; measurements are in seconds.

Vital signs—A person's essential body functions, usually defined as the pulse, body temperature, and breathing rate.

the patient's chest wall. The doctor then draws the plunger of the syringe back to create a vacuum. At this point, the patient is asked to take a deep breath and hold it. The needle is inserted into the liver and withdrawn quickly, usually within two seconds or less. The negative pressure in the syringe draws or pulls a sample of liver tissue into the biopsy needle. As soon as the needle is withdrawn, the patient can breathe normally. This step takes only a few seconds. Pressure is applied at the biopsy site to stop any bleeding and a bandage is placed over it. The liver tissue sample is placed in a cup with a 10% formalin solution and sent to the laboratory immediately. The entire procedure takes 10–15 minutes. Test results are usually available within a day.

Most patients experience minor discomfort during the procedure (up to 50% of patients), but not severe pain. According to a medical study of adult patients undergoing percutaneous liver biopsy, pain was most often described as mild to moderate (i.e., a rating of three on a scale of one to ten). Mild medications of a non-aspirin type can be given after the biopsy if the pain persists for several hours.

Preparation

The liver biopsy requires the skill of many clinicians, including the radiologist, hepatologist, and pathologist, to make the diagnosis. Nurses will assist the physician during the biopsy procedure and in caring for the patient after the procedure. Tissues are prepared for microscopic evaluation by a histologic technician in the pathology lab. The procedure is generally performed on an outpatient basis in a hospital.

Liver biopsies require some preparation by the patient. Since **aspirin** and ibuprofen (Advil, Motrin) are known to cause excessive bleeding by inhibiting platelets and lessening clotting function, the patient should avoid taking any of these medications for at least a week before the biopsy. The doctor should check the patient's records to see whether he or she is taking any other medications that may affect blood clotting. Both a **platelet count** (or **complete blood count**) and a **prothrombin time** (to assess how well the patient's **blood clots**) are performed prior to the biopsy. These tests determine whether there is an abnormally high risk of uncontrolled bleeding from the biopsy site, which may contraindicate the procedure. The patient should limit food or drink for a period of four to eight hours before the biopsy.

Patients should be told what to expect in the way of discomfort pre- and post-procedure. In addition, they should be advised about what medications they should not take before or after the biopsy. It is important for the clinician to reassure the patient concerning the safety of the procedure.

Before the procedure, the patient or family member must sign a consent form. The patient will be questioned about any history of allergy to the local anesthetic, and then will be asked to empty the bladder so that he or she will be more comfortable during the

procedure. Vital signs, including pulse rate, temperature, and breathing rate will be noted so that the doctor can tell during the procedure if the patient is having any physical problems.

When performing the liver biopsy and blood collection that precedes it, the physician and other health care providers will follow universal precautions to maintain sterility for the prevention of transmission of blood-borne pathogens.

Some patients should not have percutaneous liver biopsies. They include those with any of the following conditions:

- a platelet count below 50,000
- a prothrombin test time greater than three seconds over the reference interval, indicating a possible clotting abnormality
- a liver tumor with a large number of veins
- a large amount of abdominal fluid (ascites)
- infection anywhere in the lungs, the lining of the chest or abdominal wall, the biliary tract, or the liver
- benign tumors (angiomas) of the liver, which consist mostly of enlarged or newly formed blood vessels and may bleed heavily
- biliary obstruction (bile may leak from the biopsy site and cause an infection of the abdominal cavity)

Aftercare

Liver biopsies are now performed as outpatient procedures in most hospitals. Patients are asked to lie on their right sides for one hour and then to rest quietly for three more hours. At regular intervals, a nurse checks the patient's vital signs. If there are no complications, the patient is discharged, but will be asked to stay in an area that is within an hour from the hospital in case delayed bleeding occurs.

Patients should arrange to have a friend or relative take them home after discharge. Bed rest for a day is recommended, followed by a week of avoiding heavy work or strenuous **exercise**. The patient can immediately resume eating a normal diet.

Some mild soreness in the area of the biopsy is expected after the anesthetic wears off. Irritation of the muscle that lies over the liver can also cause mild discomfort in the shoulder for some patients. **Acetaminophen** can be taken for minor soreness, but aspirin and ibuprofen products are best avoided. The patient should, however, call the doctor if there is severe pain in the abdomen, chest, or shoulder; difficulty breathing; or persistent bleeding. These signs may indicate that there has been leakage of bile into the abdominal cavity, or that air has been introduced into the cavity around the lungs.

Results

After the biopsy, the liver sample is sent to the pathology laboratory and examined. A normal (negative) result would find no evidence of pathology in the tissue sample. It should be noted that many diseases of the liver are concentrated in one area (focal) and not spread across the liver (diffuse); an abnormality may not be detected if the sample was taken from an unaffected site. If symptoms persist, the patient may need to undergo another biopsy.

The pathologist will perform a visual inspection of the sample to note any abnormalities in appearance. In cirrhosis, the sample will be fragmented and hard. **Fatty liver**, seen in heavy drinkers, will float in the formalin solution and will be yellow. Carcinomas are white. The pathologist will also look for deposition of bile pigments (green), indicating **cholestasis** (obstruction of bile flow). In preparation for microscopic examination, the tissue will be frozen and cut into thin sections, which will be mounted on glass slides and stained with various dyes to aid in identifying microscopic structures. Using the microscope, the pathologist will examine the tissue samples and identify any abnormal cells or deposited substances such as iron or copper. In **liver cancer**, small dark malignant cells will be visible within the liver tissue. An infiltration of white blood cells may signal infection. The pathologist also checks for the number of bile ducts and determines whether they are dilated. He or she also looks at the health of the small arteries and portal veins. Fibrosis will appear as scar tissue, and fatty changes are diagnosed by the presence of lipid droplets. Many different findings may be noted, and a differential diagnosis (one out of many possibilities) can often be made. In difficult cases, other laboratory tests—such as those assessing liver function enzymes—will aid the clinician in determining the final diagnosis.

Morbidity and mortality rates

Post-biopsy complications that require hospitalization occur in approximately 1–3% of cases. Moderate pain is reported by 20% of patients, and 3% report pain severe enough to warrant intravenous pain relief. The mortality rate is approximately one in 10,000. In about 0.4% of cases, a patient with liver cancer will develop a fatal hemorrhage from a percutaneous biopsy. These fatalities result because some

WWW.BOOKBAZ.IR

liver tumors are supplied with a large number of blood vessels and thus may bleed excessively.

Risks

The complications associated with a liver biopsy are usually minor; most will occur in the first two hours following the procedure, and greater than 95% in the first 24 hours. The most significant risk is prolonged internal bleeding. Other complications from percutaneous liver biopsies include the leakage of bile or the introduction of air into the chest cavity (pneumothorax). There is also a small chance that an infection may occur. The risk that an internal organ such as the lung, gallbladder, or kidney might be punctured is decreased when using the ultrasound- or CT-guided procedure.

Alternatives

Liver biopsy is an invasive and sometimes painful procedure that is also expensive. In some instances, blood tests may provide enough information to health care providers to make an accurate diagnosis and therefore avoid a biopsy. Occasionally, a biopsy may be obtained using a laparoscope (an instrument inserted through the abdominal wall that allows the doctor to visualize the liver and obtain a sample) or during surgery if the patient is undergoing an operation on the abdomen. Imaging techniques (such as ultrasound) may also be employed during a liver biopsy, in order to allow more accurate placement of the biopsy needle.

Liver cancer

Definition

Liver cancer is a relatively rare form of cancer but has a high mortality rate. Liver cancers can be classified into two types. They are either primary, when the cancer starts in the liver itself, or metastatic, when the cancer has spread to the liver from some other part of the body.

Description

Primary liver cancer

Primary liver cancer is a relatively rare disease in the United States, representing about 2% of all malignancies and 4% of newly diagnosed cancers. Hepatocellular carcinoma (HCC) is the fifth most common cancer in the world. It is much more common outside the United States, representing 10% to 50% of malignancies in Africa and parts of Asia. Rates of HCC in men are at least two to three times higher than for women. In high–risk areas (East and Southeast Asia, sub-Saharan Africa), men are even more likely to have HCC than women.

According to the American Cancer Society, 33,140 people in the United States will be diagnosed with primary liver cancer in 2014, and 23,000 persons will die from the disease. The incidence of primary liver cancer has been rising in the United States and Canada since the mid-1990s, most likely as a result of the rising rate of **hepatitis C** infections.

TYPES OF PRIMARY LIVER CANCER. In adults, most primary liver cancers belong to one of two types: hepatomas, or hepatocellular carcinomas (HCC), which start in the liver tissue itself; and cholangiomas, or cholangiocarcinomas, which are cancers that develop in the bile ducts inside the liver. About 80% to 90% of primary liver cancers are hepatomas. In the United States, about five persons in every 200,000 will develop a hepatoma (70% to 75% of cases of primary liver cancers are HCC). In Africa and Asia, over 40 persons in 200,000 will develop this form of cancer (more than 90% of cases of primary liver are HCC). Two rare types of primary liver cancer are mixed-cell tumors and Kupffer cell **sarcomas**.

One type of primary liver cancer, called a hepatoblastoma, usually occurs in children younger than four years of age and between the ages of 12 and 15. Unlike liver cancers in adults, hepatoblastomas have a good chance of being treated successfully. Approximately 70% of children with hepatoblastomas experience complete cures. If the tumor is detected early, the survival rate is over 90%.

Metastatic liver cancer

The second major category of liver cancer, metastatic liver cancer, is about 20 times as common in the United States as primary liver cancer. Because blood from all parts of the body must pass through the liver for filtration, cancer cells from other organs and tissues easily reach the liver, where they can lodge and grow into secondary tumors. Primary cancers in the colon, stomach, pancreas, rectum, esophagus, breast, lung, or skin are the most likely to metastasize (spread) to the liver. It is not unusual for the metastatic cancer in the liver to be the first noticeable sign of a cancer that started in another organ. After **cirrhosis**, metastatic liver cancer is the most common cause of fatal **liver disease**.

Causes and symptoms

Risk factors

The exact cause of primary liver cancer is still unknown. In adults, however, certain factors are known to place some individuals at higher risk of developing liver cancer. These factors include:

- Male sex.
- Age over 60 years.
- Ethnicity. Asian Americans with cirrhosis have four times as great a chance of developing liver cancer as Caucasians with cirrhosis, and African Americans have twice the risk of Caucasians. In addition, Asians often develop liver cancer at much younger ages than either African Americans or Caucasians.
- Exposure to substances in the environment that tend to cause cancer (carcinogens). These include: a substance produced by a mold that grows on rice and peanuts (aflatoxin); thorium dioxide, which was once used as a contrast dye for x rays of the liver; vinyl chloride, used in manufacturing plastics; and cigarette smoking.
- Use of oral estrogens for birth control.
- Hereditary hemochromatosis. This is a disorder characterized by abnormally high levels of iron storage in the body. It often develops into cirrhosis.
- Cirrhosis. Hepatomas appear to be a frequent complication of cirrhosis of the liver. Between 30% and 70% of hepatoma patients also have cirrhosis. It is estimated that a patient with cirrhosis has 40 times the chance of developing a hepatoma than a person with a healthy liver.
- Exposure to hepatitis viruses: Hepatitis B (HBV), Hepatitis C (HCV), Hepatitis D (HDV), or Hepatitis G (HGV). It is estimated that 80% of worldwide HCC is associated with chronic HBV infection. In Africa and most of Asia, exposure to hepatitis B is an important factor; in Japan and some Western countries, exposure to hepatitis C is connected with a higher risk of developing liver cancer. In the United States, nearly 25% of patients with liver cancer show evidence of HBV infection. Hepatitis is commonly found among intravenous drug abusers. The 70% increase in HCC incidence in the United States is thought to be due to increasing rates of HBV and HCV infections due to increased sexual promiscuity and illicit drug needle sharing. The association between HDV and HGV and HCC is unclear at this time.

Symptoms of liver cancer

The early symptoms of primary, as well as metastatic, liver cancer are often vague and not unique to liver disorders. The long period between the beginning of the tumor's growth and the first signs of illness is the major reason why the disease has such a high mortality rate. At the time of diagnosis, patients are often fatigued, with **fever**, abdominal **pain**, and loss of appetite. They may look emaciated and generally ill. As the tumor enlarges, it stretches the membrane surrounding the liver (the capsule), causing pain in the upper abdomen on the right side. The pain may extend into the back and shoulder. Some patients develop a collection of fluid, known as **ascites**, in the abdominal cavity. Others may show signs of bleeding into the digestive tract. In addition, the tumor may block the ducts of the liver or the gall bladder, leading to

WWW.BOOKBAZ.IR

jaundice. In patients with jaundice, the whites of the eyes and the skin may turn yellow, and the urine becomes dark-colored.

Diagnosis

Physical examination

If the doctor suspects a diagnosis of liver cancer, he or she will check the patient's history for risk factors and pay close attention to the condition of the patient's abdomen during the **physical examination**. Masses or lumps in the liver and ascites can often be felt while the patient is lying flat on the examination table. The liver is usually swollen and hard in patients with liver cancer; it may be sore when the doctor presses on it. In some cases, the patient's spleen is also enlarged. The doctor may be able to hear an abnormal sound (bruit) or rubbing noise (friction rub) if he or she uses a stethoscope to listen to the blood vessels that lie near the liver. The noises are caused by the pressure of the tumor on the blood vessels.

Laboratory tests

Blood tests may be used to test liver function or to evaluate risk factors in the patient's history. Between 50% and 75% of primary liver cancer patients have abnormally high blood serum levels of a particular protein (alpha-fetoprotein or AFP). The AFP test, however, cannot be used by itself to confirm a diagnosis of liver cancer, because cirrhosis or chronic hepatitis can also produce high alpha–fetoprotein levels. Tests for alkaline phosphatase, bilirubin, lactic dehydrogenase, and other chemicals indicate that the liver is not functioning normally. About 75% of patients with liver cancer show evidence of hepatitis infection. Again, however, abnormal liver function test results are not specific for liver cancer.

Imaging studies

Imaging studies are useful in locating specific areas of abnormal tissue in the liver. Liver tumors as small as an inch across can now be detected by **ultrasound** or computed tomography scan (CT scan). Imaging studies, however, cannot tell the difference between a hepatoma and other abnormal masses or lumps of tissue (nodules) in the liver. A sample of liver tissue for biopsy is needed to make the definitive diagnosis of a primary liver cancer. CT or ultrasound can be used to guide the doctor in selecting the best location for obtaining the biopsy sample.

Chest x rays may be used to see whether the liver tumor is primary or has metastasized from a primary tumor in the lungs.

Liver biopsy

Liver biopsy is considered to provide the definite diagnosis of liver cancer. A sample of the liver or tissue fluid is removed with a fine needle and is checked under a microscope for the presence of cancer cells. In about 70% of cases, the biopsy is positive for cancer. In most cases, there is little risk to the patient from the biopsy procedure. In about 0.4% of cases, however, the patient develops a fatal hemorrhage from the biopsy because some tumors are supplied with a large number of blood vessels and bleed very easily.

Laparoscopy

The doctor may also perform a **laparoscopy** to help in the diagnosis of liver cancer. First, the doctor makes a small cut in the patient's abdomen and inserts a small, lighted tube called a laparoscope to view the area. A small piece of liver tissue is removed and examined under a microscope for the presence of cancer cells.

Treatment

Treatment of liver cancer is based on several factors, including the type of cancer (primary or metastatic); stage (early or advanced); the location of other primary cancers or metastases in the patient's body; the patient's age; and other coexisting diseases, including cirrhosis. For many patients, treatment of liver cancer is primarily intended to relieve the pain caused by the cancer but cannot cure it.

Surgery

Few liver cancers in adults can be cured by surgery because they are usually too advanced by the time they are discovered. If the cancer is contained within one lobe of the liver, and if the patient does not have either cirrhosis, jaundice, or ascites, surgery is the best treatment option. Patients who can have their entire tumor removed have the best chance for survival. Unfortunately, only about 5% of patients with metastatic cancer (from primary tumors in the colon or rectum) fall into this group. If the entire visible tumor can be removed, about 25% of patients will be cured. The operation that is performed is called a partial hepatectomy, or partial removal of the liver. The surgeon will remove either an entire lobe of the liver (a **lobectomy**) or cut out the area around the tumor (a wedge resection).

A newer technique that is reported to be safe and effective is laparoscopic radiofrequency ablation (RFA). RFA is a technique in which the surgeon places a special needle electrode in the tumor under guidance from MRI or CT scanning. When the electrode has been properly placed, a radiofrequency

current is passed through it, heating the tumor and killing the cancer cells. RFA can be used to treat tumors that are too small or too inaccessible for removal by conventional open surgery.

Chemotherapy

Some patients with metastatic cancer of the liver can have their lives prolonged for a few months by **chemotherapy**, although cure is not possible. If the tumor cannot be removed by surgery, a tube (catheter) can be placed in the main artery of the liver and an implantable infusion pump can be installed. The pump allows much higher concentrations of the cancer drug to be carried to the tumor than is possible with chemotherapy carried through the bloodstream. The drug that is used for infusion pump therapy is usually floxuridine (FUDR), given for 14-day periods alternating with 14-day rests. Systemic chemotherapy can also be used to treat liver cancer. The medications usually used are 5-fluorouracil (Adrucil, Efudex) or methotrexate (MTX, Mexate). Systemic chemotherapy does not, however, significantly lengthen the patient's survival time.

Radiation therapy

Radiation therapy is the use of high-energy rays or x rays to kill cancer cells or to shrink tumors. Its use in liver cancer, however, is only to give short–term relief from some of the symptoms. Liver cancers are not sensitive to radiation, and radiation therapy will not prolong the patient's life.

Liver transplantation

Removal of the entire liver (total hepatectomy) and **liver transplantation** can be used to treat liver cancer. However, there is a high risk of tumor recurrence and metastases after transplantation. In addition, most patients have cancer that is too far advanced at the time of diagnosis to benefit from liver transplantation.

Other therapies

Other therapeutic approaches include:

- Hepatic artery embolization with chemotherapy (chemoembolization).
- Alcohol ablation via ultrasound-guided percutaneous injection.
- Ultrasound-guided cryoablation.
- Immunotherapy with monoclonal antibodies tagged with cytotoxic agents.
- Gene therapy with retroviral vectors containing genes expressing cytotoxic agents.

Alternatives

Many patients find that alternative and complementary therapies help to reduce the **stress** associated with illness, improve immune function, and boost spirits. While there is no clinical evidence that these therapies specifically combat disease, activities such as **biofeedback**, relaxation, **therapeutic touch**, **massage therapy** and **guided imagery** have no side effects and have been reported to enhance well-being.

Several other healing therapies are sometimes used as supplemental or replacement cancer treatments, such as antineoplastons, cancell, cartilage (bovine and shark), laetrile, and mistletoe. Many of these therapies have not been the subject of safety and efficacy trials by the National Cancer Institute (NCI). The NCI has conducted trials on cancell, laetrile, and other alternative therapies and found no anticancer activity. These treatments have varying effectiveness and safety considerations. Patients using any alternative remedy should first consult their doctor in order to prevent harmful side effects or interactions with traditional cancer treatment.

Prognosis

Liver cancer has a very poor prognosis because it is often not diagnosed until it has metastasized. Fewer than 10% of patients survive three years after the initial diagnosis; the overall five-year survival rate for patients with hepatomas is around 4%. Most patients with primary liver cancer die within six months of diagnosis, usually from liver failure; fewer than 5% are cured of the disease. Patients with liver cancers that metastasized from cancers in the colon live slightly longer than those whose cancers spread from cancers in the stomach or pancreas.

African American and Hispanic patients have much lower 5-year survival rates than Caucasian patients. It is not yet known, however, whether cultural differences as well as biological factors may be partly responsible for the variation in survival rates.

Prevention

There are no useful strategies at present for preventing metastatic cancers of the liver. Primary liver cancers, however, are 75% to 80% preventable. Current strategies focus on widespread **vaccination** for **hepatitis B**, early treatment of hereditary **hemochromatosis**, and screening of high-risk patients with alpha–fetoprotein testing and ultrasound examinations.

Lifestyle factors that can be modified in order to prevent liver cancer include avoidance of exposure to toxic chemicals and foods harboring molds that produce aflatoxin. Most important, however, is avoidance

KEY TERMS

Aflatoxin—A substance produced by molds that grow on rice and peanuts. Exposure to aflatoxin is thought to explain the high rates of primary liver cancer in Africa and parts of Asia.

Alpha-fetoprotein—A protein in blood serum that is found in abnormally high concentrations in most patients with primary liver cancer.

Cirrhosis—A chronic degenerative disease of the liver, in which normal cells are replaced by fibrous tissue. Cirrhosis is a major risk factor for the later development of liver cancer.

Cryoablation—A technique for removing cancerous tissue by killing it with extreme cold.

Hepatitis—A viral disease characterized by inflammation of the liver cells (hepatocytes). People infected with hepatitis B or hepatitis C virus are at an increased risk for developing liver cancer.

Metastatic cancer—A cancer that has spread to an organ or tissue from a primary cancer located elsewhere in the body.

Radiofrequency ablation—A technique for removing a tumor by heating it with a radiofrequency current passed through a needle electrode.

of alcohol and drug abuse. Alcohol abuse is responsible for 60% to 75% of cases of cirrhosis, which is a major risk factor for eventual development of primary liver cancer. Hepatitis is a widespread disease among persons who abuse intravenous drugs.

Liver disease

Definition

Liver disease is a general term for any damage that reduces the functioning of the liver.

Description

The liver is a large, solid organ located in the upper right-hand side of the abdomen. Most of the

liver lies under the rib cage, which helps protect it from physical injury. The liver is made up of two main lobes and two minor lobes and has a total weight in adults of about 3.5 lb (1.6 kg).

Within the liver are tiny ducts (tubes) that collect bile, a product secreted by the liver. Bile is stored in to the gall bladder and then released into the intestines after meals to help in the digestion of fats and the absorption of certain **vitamins**. This system of bile production by the liver, transport through the bile ducts, and storage in the gall bladder is called the biliary system. Damage to this system is called biliary disease.

The liver receives blood that comes directly from the intestines. At any given time the liver contains about 13% of the blood circulating in the body. This blood is rich in nutruents (food, vitamins, and **minerals**) that the body needs to function. Some of the most important functions of the liver are to process these nutrients.

Important functions of the liver include:

- manufacturing and regulating the production of proteins. The most important proteins made in the liver are albumin, which helps maintain blood volume, and clotting factors to help regulate blood clotting.
- making and storing fatty acids and cholesterol.
- forming and releasing bile
- processing and storing sugars in the form of glycogen, which can then be re-converted into energy
- Storing iron, an important element in blood formation
- Breaking down (detoxifying) alcohol, drugs, and environmental poisons so that they can be removed from the body.
- Processing and removing bilirubin, a product released when red blood cells break down, and ammonia, a toxic waste product of protein breakdown.
- Defending against infection by removing bacteria from the blood and making chemicals necessary to the functioning of the immune system.

Although the liver is the only organ that has the capacity to grow back, or regenerate, after injury or damage, sometimes the damage is too great for it to heal. The American Association for the Study of Liver Disease estimates that about 25 million Americans experience a liver-related disease each year. Individuals cannot live without a functioning liver. The ability to transplant livers is improving, **liver transplantation** is not nearly as common or successful as **kidney transplantation**.

Because the liver has many vital functions, there are many types of liver disease. The American Liver Foundation estimates that over 20,000 Americans die of chronic liver disease each year and another 360,000 are hospitalized. Individuals cannot live without a functioning liver.

Congenital Liver Diseases

Congenital liver diseases are disorders that are present at birth. Inherited liver diseases and disorders include:

- Alagile syndrome, a disorder that causes withering of the bile ducts. This disease occurs in less than 1 in 100,000 individuals.
- Alpha 1-antitrypsin deficiency, an inborn error in metabolism and the most common type of genetic liver disease.
- Galactosemia, a hereditary metabolic disease in which the liver is unable to break down the sugar galactose found in milk. It occurs in about one in every 20,000 births.
- Hematochromatosis, a hereditary metabolic disorder in which too much iron is absorbed from the diet and stored in the liver. This disease affects over one million Americans.
- Porphyria, a disorder in which the component of blood that contains iron is not correctly formed.
- Tyrosinemia, a rare inherited error in metabolism that causes severe liver disease in infants and children. It affects fewer than 200,000 individuals in the United States.
- Type I glycogen storage disease, a lack of the enzyme that helps regulate blood glucose (sugar) levels.
- Wilson's disease, an inherited disorder in which copper is accumulated in the liver and nervous system.

Acquired Liver Diseases

Many liver diseases are acquired from infection and exposure of the liver to toxic substances such as alcohol or drugs. In some areas of the world (although not the United States) liver parasites are a common cause of liver disease. In the United States, the most common acquired liver diseases are **hepatitis A**, B, and C and **cirrhosis**. Hepatitis A causes an acute (short-term) illness and is caused by a virus found in food or drinking water contaminated with feces. Hepatitis A infects between 125,000 and 250,000 people in the United States each year and causes about 100 deaths annually.

Hepatitis B is a viral infection spread by blood exchange and sexual contact with an infected person. It can be passed from an infected mother to her fetus.

WWW.BOOKBAZ.IR

In most people hepatitis B is a short-term illness that causes mild symptoms such as **fatigue**, but in 2–6% of people, the disease lasts a long time and causes permanent liver damage. More than 75,000 people in the United States become infected with hepatitis B each year. Chinese Americans have a hepatitis B infection rate five times that of Caucasian Americans.

Hepatitis C is caused by a virus spread mainly through contact with the blood of an infected person, such as through sharing needles to inject drugs or from a mother to a fetus. Individuals infected with hepatitis C virus may not feel sick or know that they are infected for many years, but the disease can increase the likelihood of developing **liver cancer** of cirrhosis. The American Liver Foundation estimates that 4 million Americans are infected with hepatitis C, resulting in 10,000–12,000 deaths each year. About 70% of individuals who are infected do not know that they have the virus. African Americans have the highest rate of hepatitis C infections and are twice as likely to be infected with hepatitis C as Caucasian Americans.

Cirrhosis of the liver involves the formation of permanent scar tissue in the liver and loss of liver function. It is often caused by chronic alcohol abuse (alcoholic liver disease), but it can also be caused by diseases such as hepatitis. Cirrhosis interferes with blood flow through the liver and can raise pressure in blood vessels supplying the liver and decrease the absorption of nutrients from the blood, leading to **malnutrition**. The liver of individuals with cirrhosis is also less effective in removing toxic wastes from the blood. Cirrhosis can be fatal.

Over 800 over-the-counter and prescription drugs, as well as illicit street drugs, can cause liver damage. One of the most common drugs to cause liver damage is **acetaminophen** (Tylenol) when taken at high doses or by individuals who already have some liver damage. Exposure to toxic chemicals, physical injury, and blockage of the bile ducts call also cause liver damage.

Liver cancer can either develop first in the liver (primary liver cancer) or spread there from another site (metastasized cancer). About 16,000 new cases of primary liver cancer are diagnosed each year, most commonly in middle age and older men. Although the cause of liver cancer is unclear, it appears to be associated with chronic infections of hepatitis B and C.

Causes and symptoms

The causes of liver disease are many and varied. Leading causes are viral infection, alcohol abuse, and inherited disease. A common symptoms of liver disease are **jaundice**. With jaundice, the skin and the whites of the eyes take on a yellowish color as a result of the accumulation of bilirubin and bile pigments in the blood. This is a sign that the liver or the biliary system is not functioning properly. Other symptoms of liver disease include an enlarged liver and swollen abdomen, nausea, **vomiting**, weight loss, and fatigue. Some infections cause flu-like symptoms of **fever**, **headache**, and weakness.

Diagnosis

Liver function tests, sometimes called a liver panel, measure various enzymes, proteins, and waste products in the blood. These readings can tell a physician whether the liver is damaged and give an idea of how well it is functioning. Liver function tests are the most common way to diagnose liver damage. Based on the results of a liver panel, additional blood tests for infection, a **liver biopsy**, or liver scan may be done to pinpoint the reason for loss of function.

Treatment

Treatments depend on the type of liver disease an individual has. Many liver diseases are treated with altered **diets**, abstinence from alcohol, and medication. Hepatitis can be treated with antiviral medications such as interferon or ribavirin. Liver cancer is treated with **chemotherapy**, radiation, and surgery. More than 300 clinical trials are enrolling patients with various types of liver disease in experimental treatment programs. Information on current clinical trials can be found at www.clinicaltrials.gov.

If the liver fails completely, a liver transplant is possible. About 6,000 liver transplants are performed in the United States annually. Donors and recipients are matched on the basis of blood type and must also be about the same weight. There is no machine like a **kidney dialysis** machine to perform the functions of the liver while individuals are awaiting a transplant. About 1,500 people die awaiting a liver donor, and about 17,000 more are on the waiting list awaiting a donated liver. Livers to be transplanted can come from either a living donor or a deceased donor.

Alternatives

A great deal of interest in alternative treatments for hepatitis C has resulted in a review of alternative and complementary treatments by the National Center for Complementary and Alternative Medicine (NCCAM), a division of the United States National Institutes of Health. Although there was in 2014 not enough solid experimental evidence to show that any herbal treatments cured hepatitis C, the most promising herbal treatment was an extract of milk thistle (*Silybum marianum*), a plant in the aster family that

KEY TERMS

Biliary—Relating to the system that produces and transports bile.

Bile—A yellowish-green material secreted by the liver, stored by the gall bladder, and emptied into the small intestine to aid in the digestion and absorption of fats.

Bilirubin—A reddish-yellow substance that results from the breakdown of aging red blood cells. It is found in blood and bile, and if it accumulates in large quantities can cause jaundice.

Biopsy—A diagnostic procedure in which a small sample of tissue is obtained and examined under the microscope to determine they type and stage of a disease.

Congenital—Present at birth.

Feces—Waste products eliminated from the large intestine; excrement.

Jaundice—A yellowish tinge to the skin and whites of the eyes that indicates malfunction of the biliary system and/or liver and build up of bile components in the blood.

has been used for centuries in Europe to treat liver disease and jaundice. Some studies suggested that extracts of milk thistle promoted the growth of certain types of liver cells and acted as an anti-oxidant to protect the liver while producing few unwanted side effects. Other studies showed no protective effects.

Licorice root (*Glycyrrhiza glabra*) was also reviewed by NCCAM. Some studies suggested that licorice root had antiviral properties, however this herb did not reduce the amount of hepatitis C virus circulating in the blood. Long term use of licorice root can have serious, health-threatening side effects.

Other alternative treatments studied by NCCAM include **ginseng** (*Panax quinquefolius* and *Panax ginseng*), which they concluded might possibly have a positive effect on the liver, especially in the elderly, and schisandra (*Schisandra chinensis* and *Schisandra sphenanthera*) used in Chinese medicine, which seemed to have a liver-protective effect in laboratory animals. Thymus extract and colloidal silver were found to be ineffective in treating liver disease.

Prognosis

The course of liver disease depends on the type of disease. Many individuals recover completely from infections of hepatitis A and B. However, if liver scarring occurs, the effects are irreversible. The initial success rate for liver transplants is good, with about 90% of individuals receiving a liver transplant are alive one year after the transplant operation. However, no alternative treatments produced a better outcome than traditional treatments of hepatitis C.

Prevention

Prevention is an effective way to avoid liver disease. Vaccines exist for hepatitis A and B (but not hepatitis C), although many individuals remain unvaccinated. In addition to **vaccination**, individuals can decrease the likelihood of developing liver disease by

- practicing safe sex
- avoiding sharing needles
- eating a healthy, balanced diet
- taking medications as prescribed
- avoiding drinking alcohol.

Liver encephalopathy

Definition

Liver **encephalopathy** is a potentially life-threatening disease in which toxic substances accumulate in the blood because the liver can no longer remove these excess substances, eventually causing decreased function in the brain of persons with advanced **liver disease**. The condition results in a disturbance in central

WWW.BOOKBAZ.IR

nervous system function. Liver encephalopathy comprises a spectrum of neuropsychiatric conditions. Also known as hepatic encephalopathy (HE) and hepatic **coma** or coma hepaticum (during its advanced stage), this condition can cause confusion, disorientation, abnormal neurological signs, loss of consciousness, and eventually death. It is also sometimes referred to as portosystemic encephalopathy (PSE) and portal-systemic encephalopathy.

Description

A normally functioning liver metabolizes and detoxifies substances formed in the body during the digestive process. Impaired liver function allows substances such as ammonia (formed when the body digests protein), some fatty acids, phenol, and mercaptans to escape into the bloodstream. From there, they may penetrate the blood-brain barrier, affect the central nervous system (CNS), and lead to liver encephalopathy. WebMD describes liver encephalopathy as "a brain disorder that develops in some individuals with liver disease." The online health organization goes on to state that "Hepatic encephalopathy is a complex disorder that encompasses a spectrum or continuum of disease that ranges from a subtle condition with no outward signs or symptoms to a severe form that can cause serious, life-threatening complications."

Four stages of the disease are often used to classify its severity. Stage 1, mild hepatic encephalopathy, causes patients to have trouble concentrating, often have sleep problems, and have severe mood swings (they can be euphoric, followed by anxious). The hands of these patients may shake, and they may have trouble writing legibly. Stage 2, moderate hepatic encephalopathy, causes sufferers to be lethargic or apathetic. They are forgetful and have problems doing basic mathematics problems (such as, addition and subtraction). Their speech is often slurred, and they often behave erratically. In Stage 3, patients are normally very sleepy even during the day and may even faint. Called severe hepatic encephalopathy, this stage prevents patients performing math problems; individuals act strangely and oftentimes are anxious and fearful in normal day-to-day situations. They have gross disorientation. In Stage 4, also called the final stage, patients are unconscious—in a comatose state, unresponsive to verbal or noxious stimuli.

Demographics

According to the American Liver Foundation, one out of every ten Americans has liver disease, which corresponds to about 30 million people. Further, over 8 million people are at risk for liver disease (**cirrhosis**), and thus for liver encephalopathy, in the United States at any given point in time. Over 100 types of liver disease occur. Although liver disease is often associated with a poor lifestyle or with advanced age, it can affect anyone, even those with healthy and active lives. Hepatic coma, or the advanced stage for liver encephalopathy, is most common in patients with chronic liver disease. It occurs in 50–70% of all those with cirrhosis.

Causes and symptoms

Liver encephalopathy is caused by liver disorders. These disorders may be acute and potentially reversible or they may be chronic and associated with long-term liver disease. Various disorders of the liver include those that reduce its function, such as cirrhosis and hepatitis, and conditions that result because blood is not allowed to properly circulate through the liver. The disease is frequently associated with the following conditions, disorders, or activities:

- acute or chronic liver disease
- kidney disease
- acute liver disease
- gastrointestinal bleeding, such as from the esophagus, intestines, or stomach
- azotemia, the accumulation of nitrogen-containing compounds (such as urea) in the blood
- low level of oxygen in the body
- inherited disorders that disrupt the process by which nitrogen is decomposed and excreted
- the use of shunts (devices implanted in the body to redirect the flow of fluid from one vessel to another); also complications from their insertion into the body
- electrolyte imbalances, including low levels of potassium (hypokalemia) and abnormally alkaline blood pH (alkalosis); these imbalances may result from the overuse of sedatives, analgesics, or diuretics; reduced levels of oxygen (hypoxia); or withdrawal of excessive amounts of body fluid (hypovolemia)
- dehydration
- constipation, which may increase the body's nitrogen load
- surgery
- diets containing large amounts of protein
- infections

Binge drinking and acute infection are common causes of liver encephalopathy in patients with long-standing liver disease.

Symptoms of liver encephalopathy range from almost unnoticeable changes in personality, energy levels, and thinking patterns to deep coma.

Inability to reproduce a simple design (**apraxia**) and deterioration of handwriting are common symptoms of early encephalopathy. Decreased brain function can also cause inappropriate behavior, lack of interest in personal grooming, mood swings, and uncharacteristically poor judgment.

The patient may be less alert than usual and develop new sleep patterns. Movement may be sluggish and labored, and speech may be slurred and slow.

As the disease progresses, patients become confused, drowsy, disoriented, and forgetful. The breath and urine acquires a sweet, musky odor. The hands shake, the outstretched arms flap (asterixis or liver flap), and patients may lapse into unconsciousness. As coma deepens, reflexes may be heightened (hyperreflexia). The toes sometimes splay when the sole of the foot is stroked (Babinski reflex).

Agitation or overly excited behavior may occasionally occur in children and in adults who suddenly develop severe symptoms. Seizures are uncommon.

Diagnosis

The absence of sensitive, reliable tests for liver encephalopathy makes the physician's personal observations and professional judgment the most valuable diagnostic tools available.

Confusion, disorientation, and other indications of impaired brain function strongly suggest encephalopathy in patients known to have liver disease. Computed tomography (CT) scans and examination of the head and spinal fluid do not provide accurate diagnostic clues. Elevated arterial ammonia levels are almost always present in hepatic coma, but levels are not necessarily correlated with the severity or extent of the disease.

Magnetic resonance imaging (MRI) can show severe brain swelling that often occurs prior to coma, and **electroencephalography** (EEG) detects abnormal brain waves even in patients with early, mild symptoms. Blood and urine analyses can provide important information about the cause of encephalopathy in patients suspected of taking large quantities of sedatives or other drugs. **Liver function tests** are also used, as are tests to determine the levels of serum ammonia, **sodium**, and potassium in the blood. Blood urea nitrogen (BUN) and creatinine tests are used to determine the level of kidney function in the body. Overall, **neuropsychological testing** often ranges from a single test to a series of tests. The tests most frequently used for the diagnosis of liver encephalopathy are the number connection test (parts A and B), the digit symbol test, and the block design test.

Treatment

This condition may disappear if the cause of symptoms is eliminated. In other cases, treatment is designed to improve liver function as much as possible; remove or relieve factors that worsen symptoms; and decrease the body's production of poisonous substances. Further, any gastrointestinal bleeding must be eliminated as soon as possible. Concurrently, the intestines need to be emptied of blood. Further treatment for kidney failure, electrolyte imbalance, and infections must also be performed.

All nonessential medications are discontinued during the treatment for liver encephalopathy. Medicines that are broken down by the liver should be strictly avoided, such as sedatives and tranquilizers. Soft restraints are recommended in place of sedatives for patients who become agitated.

Enemas or **laxatives** are used to stimulate expulsion of toxic intestinal products. All or most protein is eliminated from the diet, and supplemental feeding may be necessary to replenish lost calories. Regular doses of neomycin (Neobiotic), taken orally or administered to comatose patients in liquid form through a tube, may be used to decrease production of protein-digesting bacteria in the bowel.

Lactulose, a synthetic sugar, changes the characteristics of intestinal bacteria, decreases the amount of ammonia accumulated in the body, and has laxative properties. The patient is given hourly doses of lactulose syrup until **diarrhea** occurs, then dosage is adjusted to maintain regular bowel function. Lactulose and dietary-protein restrictions may be used to control chronic encephalopathy. Rifaximin, a type of semisynthetic antibiotic, is also effective in the treatment of liver encephalopathy.

Prognosis

Acute liver encephalopathy may be reversible if the responsible factor is identified and removed or treated. Patients whose condition is the result of chronic liver disease may recover completely after the underlying cause is corrected. However, chronic liver encephalopathy often becomes worse or continues to adversely affect afflicted patients. Both acute and chronic forms of the disease have the potential to result in coma and even death. Possible complications of liver encephalopathy include brain herniation and

Cirrhosis—A serious disease of the liver caused by chronic damage to its cells and the eventual formation of scar tissue (fibrosis).

Coma—A condition of deep unconsciousness from which the person cannot be aroused.

Electrolytes—Substances that conduct electricity when they are in solution. In the body, electrolytes in the blood and tissues enable nerve impulses to flow normally.

swelling, along with increased risk for kidney failure, **sepsis**, **respiratory failure**, and cardiovascular collapse. Permanent nervous system damage is also possible.

Despite intensive treatment, encephalopathy caused by acute liver inflammation (fulminant hepatitis) is fatal for as many as 80% of patients. Those with chronic liver failure often die in hepatic coma.

Prevention

The successful treatment of liver disorders can prevent liver encephalopathy in some cases. The medical community recommends, overall, that intravenous drug use and heavy alcoholic drinking be avoided in order to prevent many liver disorders.

Liver function tests

Definition

Liver function tests, or LFTs, include tests that are routinely measured in all clinical laboratories. LFTs include bilirubin, a compound formed by the breakdown of hemoglobin; ammonia, a breakdown product of protein that is normally converted into urea by the liver before being excreted by the kidneys; proteins that are made by the liver, including total protein, albumin, prothrombin, and fibrinogen; **cholesterol** and **triglycerides**, which are made and excreted via the liver; and the enzymes alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase (ALP), gamma-glutamyl transferase (GGT), and lactate dehydrogenase (LDH). Other liver function tests include serological tests (to demonstrate antibodies); DNA tests for hepatitis and other viruses; and tests for antimitochondrial and smooth muscle antibodies, transthyretin (prealbumin), **protein electrophoresis**, bile acids,

alpha-fetoprotein, and other enzymes that help differentiate necrotic (characterized by the death of tissue) versus obstructive **liver disease**.

Purpose

Liver function tests done individually do not give the physician much information, but used in combination with a patient's medical history, **physical examination**, and imaging studies, they contribute to making an accurate diagnosis of the specific liver disorder. Different tests will show abnormalities in response to liver inflammation; liver injury due to drugs, alcohol, toxins, or viruses; liver malfunction due to blockage of the flow of bile; and liver cancers.

Description

The liver is the largest and one of the most important organs in the body. It regulates the levels of most of the biomolecules found in the blood and acts with the kidneys to clear the blood of drugs and toxic substances. The liver metabolizes these products, alters their chemical structure, makes them water soluble, and excretes them in bile. Laboratory tests for total protein, albumin, ammonia, transthyretin, and cholesterol are markers for the synthetic (chemical-producing) function of the liver. Tests for cholesterol, bilirubin, ALP, and bile salts are measures of the secretory (excretory) function of the liver. The enzymes ALT, AST, GGT, LDH, and tests for viruses are markers for liver injury.

Some liver function tests are used to determine if the liver has been damaged or its function impaired. Elevations of these markers for liver injury or disease tell the physician that something is wrong with the liver. ALT and bilirubin are the two primary tests used largely for this purpose. Bilirubin is measured by two tests, called total and direct bilirubin. While total bilirubin is elevated in various liver diseases, it is also increased in certain (hemolytic) **anemias** caused by increased red blood cell turnover. Neonatal hyperbilirubinemia (**jaundice**) is a condition caused by an immature liver than cannot conjugate (process) the bilirubin. The level of total bilirubin in the blood becomes elevated and must be monitored closely in order to prevent damage to the brain caused by unconjugated bilirubin, which has a high affinity for brain tissue. Bilirubin levels can be decreased by exposing the baby to UV light. Direct bilirubin is formed only by the liver, and so it is specific for hepatic or biliary disease. Its concentration in the blood is very low (0–0.2 mg/dL), so even slight increases are significant. Highest levels of direct bilirubin are seen in obstructive liver diseases. However, direct bilirubin is not sensitive to all forms of liver disease and is not always elevated in the earliest stages of disease. Therefore, ALT is needed to help determine the diagnosis.

Although ALT is present in other tissues, its concentration in the liver is far greater than any other tissue. The enzyme is very sensitive to liver injury. Consequently, if ALT or direct bilirubin is increased, then some form of liver disease is likely. If both are normal, then liver disease is unlikely.

These two tests, along with others, are used to help make a diagnosis. The most useful tests for this purpose are the liver function enzymes and the ratio of direct to total bilirubin. These tests are used to differentiate diseases characterized primarily by hepatocellular damage (**necrosis**, or cell death) from those characterized by obstructive damage (**cholestasis** or blockage of bile flow). Liver cell damage may be caused by viral hepatitis, hepatitis induced by drugs or poisons (toxic hepatitis), **alcoholic hepatitis**, hypoxic necrosis (a consequence of **congestive heart failure**), chronic hepatitis, and **cirrhosis** of the liver. Obstructive liver diseases include intrahepatic (within the liver) obstructive disease or extrahepatic (outside the liver) obstruction. In both cases, the direct bilirubin is often greatly elevated because the liver can conjugate the bilirubin, but this direct bilirubin cannot be excreted via the bile. In such cases the ratio of direct to total bilirubin is greater than 0.4.

Aspartate aminotransferase (AST) is not as specific for liver disease as ALT. However, differentiation of acute and chronic forms of liver disease is aided by examining the ratio of ALT to AST, called the DeRitis ratio. In acute hepatitis, Reye's syndrome, and **infectious mononucleosis**, the ALT predominates. However, in alcoholic liver disease, chronic hepatitis, and cirrhosis, the AST predominates.

Alkaline phosphatase (ALP) is increased in obstructive liver diseases, but it is not specific for the liver. Increases are commonly seen in bone diseases, late **pregnancy**, leukemia, and some other malignancies. The enzyme gamma-glutamyl transferase (GGT) is used to help differentiate the source of an elevated ALP. GGT is greatly increased in obstructive jaundice, alcoholic liver disease, and hepatic cancer. When the increase in GGT is two or more times greater than the increase in ALP, the source of the ALP is considered to be from the liver. When the increase in GGT is five or more times the increase in ALP, this points to a diagnosis of alcoholic hepatitis. GGT, but not AST and ALT, is elevated in the first stages of liver inflammation due to alcohol consumption, and GGT is

WWW.BOOKBAZ.IR

useful as a marker for excessive drinking. GGT has been shown to rise after acute persistent alcohol ingestion and then fall when alcohol is avoided.

Lactate dehydrogenase (LDH) is found in almost all cells in the body. LDH is increased in megaloblastic and hemolytic anemias, leukemias and lymphomas, myocardial infarction, infectious mononucleosis, muscle wasting diseases, and both necrotic and obstructive jaundice. LDH is markedly increased in most cases of **liver cancer**. An enzyme pattern showing a marked increase in LDH and to a lesser degree ALP with only slightly increased transaminases (AST and ALT) is seen in cancer of the liver.

Some liver function tests are not sensitive enough to be used for diagnostic purposes but are elevated in severe or chronic liver diseases. These tests are used primarily to indicate the extent of damage to the liver. Tests in this category include ammonia, total protein, albumin, cholesterol, transthyretin, fibrinogen, and the **prothrombin time**.

Analysis of blood ammonia aids in the diagnosis of severe liver diseases and helps to monitor the course of these diseases. Together with the AST and the ALT, ammonia levels are used to confirm a diagnosis of Reye's syndrome, a rare disorder usually seen in children and associated with infection and **aspirin** intake. Reye's syndrome is characterized by brain and liver damage following an upper respiratory tract infection, **chickenpox**, or **influenza**. Ammonia levels are also helpful in the diagnosis and treatment of hepatic **encephalopathy**, a serious brain condition caused by the accumulated toxins that result from liver disease and liver failure. Ammonia levels in the blood are normally very low. Increasing ammonia signals end-stage liver disease and a high risk of hepatic **coma**.

Albumin is the protein found in the highest concentration in blood, making up over half of the protein mass. A persistently low albumin in liver disease is a sign of progressive liver failure. In the acute stages of liver disease, proteins such as transthyretin (prealbumin) may be measured to give an indication of the severity of the disease.

Cholesterol is synthesized by the liver. Its balance is maintained by the liver's ability to remove cholesterol from lipoproteins and use it to produce bile acids and salts that it excretes into the bile ducts. In obstructive jaundice caused by stones, biliary tract scarring, or cancer, the bile cannot be eliminated. Cholesterol and triglycerides may accumulate in the blood as low-density lipoprotein (LDL) cholesterol. In acute necrotic liver diseases, triglycerides may be elevated. In liver failure caused by necrosis, the liver's ability to synthesize cholesterol is reduced, and blood levels may be low.

The liver is responsible for production of the **vitamin K** clotting factors. In obstructive liver diseases, a deficiency of vitamin K-derived clotting factors results from failure to absorb vitamin K. In obstructive jaundice, an intramuscular injection of vitamin K will be given. In severe necrotic disease, the liver cannot synthesize clotting factors from vitamin K.

The most prevalent liver disease is viral hepatitis. Tests for this condition include a variety of antigen and antibody markers and nucleic acid tests. In addition to hepatitis A–E, viral hepatitis may be caused by **Epstein-Barr virus** (EBV) and cytomegalovirus (CMV) infections of the liver. Tests for these viruses, such as the infectious mononucleosis antibody test, anti-viral capsid antigen test (anti-VCA), and anti-CMV test, are useful in diagnosing these infections.

Liver disease may be caused by autoimmune mechanisms in which autoantibodies destroy liver cells. Autoimmune necrosis is associated with **systemic lupus erythematosus** and chronic viral hepatitis, usually caused by **hepatitis B** and **hepatitis C** virus infections. These conditions give rise to anti-smooth muscle antibodies and anti-nuclear antibodies, and tests for these are useful markers for chronic hepatitis. Antibodies to mitochondrial antigens (antimitochondrial antibodies) are found in the blood of more than 90% of persons with **primary biliary cirrhosis**.

Precautions

Blood for LFTs is collected by sticking a needle into a vein. The nurse or phlebotomist (person trained to draw blood) performing the procedure must be careful to clean the skin before sticking in the needle.

Drug interactions

Various drugs and substances, as well as other factors, may affect test results.

BILIRUBIN. Drugs that may cause increased blood levels of total bilirubin include anabolic **steroids**, **antibiotics**, antimalarials, ascorbic acid, chlorpropamide (Diabinese), codeine, **diuretics**, epinephrine, **oral contraceptives**, and **vitamin A**.

AMMONIA. Muscular exertion can increase ammonia levels, while cigarette **smoking** produces significant increases within one hour of inhalation. Drugs that may cause increased levels include alcohol, **barbiturates**, **narcotics**, and diuretics. Drugs that may decrease levels include antibiotics, levodopa, lactobacillus, and potassium salts.

ALT. Drugs that may increase ALT levels include **acetaminophen**, ampicillin, codeine, dicumarol, indomethacin, methotrexate, oral contraceptives, **tetracyclines**, and verapamil. Previous intramuscular injections may cause elevated levels.

GGT. Drugs that may cause increased GGT levels include alcohol, phenytoin, and phenobarbital. Drugs that may cause decreased levels include oral contraceptives.

LDH. Strenuous activity may raise levels of LDH. Alcohol, anesthetics, aspirin, narcotics, procainamide, and fluoride may also raise levels. Ascorbic acid (vitamin C) can lower levels of LDH.

Preparation

Before a liver function test, patients are asked to fast and to inform clinicians of all drugs, even over-the-counter drugs, that they are taking. Many times, however,liver function tests are done on an emergency basis, so **fasting** and obtaining a medical history may not be possible.

Aftercare

Patients will have blood drawn into a vacuum tube and may experience some **pain** and burning at the site of injection. A gauze bandage may be placed over the site to prevent further bleeding. If the patient is suffering from severe liver disease, he or she may lack clotting factors. The nurse or caregiver should be careful to monitor bleeding in these patients after obtaining blood.

Results

Reference ranges vary from laboratory to laboratory and also depend upon the method used. However, normal values are generally framed by the following ranges:

- ALT: 5–35 IU/L (Values for the elderly may be slightly higher, and values also may be higher in men and in African Americans.)
- AST: 0–35 IU/L
- ALP: 30–120 IU/L (ALP is higher in children, older adults, and pregnant females.)
- GGT:
  - males: 2–30 U/L
  - females: 1–24 U/L
- LDH:
  - 0–4 days old: 290–775 U/L
  - 4–10 days: 545–2000 U/L
  - 10 days–24 months: 180–430 U/L
  - 2–12 years: 110–295 U/L
  - 12–60 years: 100–190 U/L
  - 60 years: >110–210 U/L
- bilirubin:
  - total bilirubin: 0.1–1.0 mg/dL
  - indirect bilirubin: 0.2–0.8 mg/dL
  - direct bilirubin: 0.0–0.3 mg/dL
  - critical values for adults: greater than 1.2 mg/dL
  - total bilirubin for newborns: 1–12 mg/dL
  - critical values for newborns (requiring immediate treatment): greater than 15 mg/dL
- ammonia: 10–70 micrograms per dL (heparinized plasma)—normal values for this test vary widely
- albumin: 3.2–5.4 g/L

Abnormal

ALT. Values are significantly increased in cases of hepatitis and moderately increased in cirrhosis, liver tumor, obstructive jaundice, and severe **burns**. Values are mildly increased in **pancreatitis**, **heart attack**, infectious mononucleosis, and **shock**. The measure of ALT is most useful when compared with ALP levels.

AST. High levels may indicate liver cell damage, hepatitis, heart attack, **heart failure**, or **gallstones**.

ALP. Elevated levels occur in diseases that impair bile formation (cholestasis). ALP may also be elevated in many other liver disorders, as well as some lung cancers (bronchogenic carcinoma) and Hodgkin's lymphoma. However, elevated ALP levels can occur in otherwise healthy people, especially among older people.

GGT. Increased levels of GGT are diagnostic of hepatitis, cirrhosis, liver tumor or metastasis, and injury from drugs toxic to the liver. GGT levels may increase with alcohol ingestion, heart attack, pancreatitis, infectious mononucleosis, and Reye's syndrome.

LDH. Elevated LDH is seen with heart attack, **kidney disease**, hemolysis, viral hepatitis, infectious mononucleosis, Hodgkin's disease, abdominal and lung cancers, **germ cell tumors**, progressive **muscular dystrophy**, and **pulmonary embolism**. LD is not normally elevated in cirrhosis.

BILIRUBIN. Increased indirect or total bilirubin levels can indicate various serious anemias, including hemolytic disease of the newborn and **transfusion** reaction. Increased direct bilirubin levels can be diagnostic of bile duct obstruction, gallstones, cirrhosis, or

Bile acid—A detergent that is made in the liver and excreted into the intestine to aid in the absorption of fats.

Biliary—Relating to bile.

Cirrhosis—A liver disease where there is a loss of normal liver tissues, replaced by scar tissue. This is usually caused by chronic alcohol abuse, but also can be caused by blockage of the bile ducts.

Detoxification—A process of altering the chemical structure of a compound to make it less toxic.

Hepatitis—Inflammation of the liver.

Hepatocyte—Liver cell.

Isoenzyme—One of a group of enzymes that bring about the same reactions on the same chemicals but are different in their physical properties.

Jaundice—Hyperbilirubinemia, or too much bilirubin in the blood. Bilirubin will be deposited in the skin and the mucosal membranes. The whites of the eyes and the skin appear yellow.

Lipoprotein—A chemical combination of a protein and a lipid (fats).

Neonatal jaundice—A disorder in newborns where the liver is too premature to conjugate bilirubin, which builds up in the blood.

hepatitis. It is important to note that if total bilirubin levels in the newborn reach or exceed critical levels, exchange transfusion is necessary to avoid kernicterus, a condition that causes brain damage from bilirubin in the brain.

AMMONIA. Increased levels are seen in primary liver cell disease, Reye's syndrome, severe heart failure, hemolytic disease of the newborn, and hepatic encephalopathy.

ALBUMIN. Albumin levels are increased due to **dehydration**. They are lowered due to a decrease in synthesis of the protein, which is seen in severe liver failure and in conditions such as burns or renal disease, which cause loss of albumin from the blood.

Liver nuclear medicine scan

Definition

A liver scan is a diagnostic procedure to evaluate the liver for suspected disease. A radioactive substance which concentrates in the liver is injected intravenously and the image of its distribution in the body is analyzed to diagnose certain abnormalities.

Purpose

In the past, liver scans were used to evaluate the liver in a wide variety of situations. It was considered a useful study to detect abnormalities, but was often not able to establish a specific diagnosis. In the 1990s, radionuclide imaging of the liver (use of a radioactive

form of cobalt or iodine) evolved into a more specialized study, used to identify individual diseases or conditions. This is accomplished by using different radioisotopes precisely designed to further evaluate a particular case. Isotopes are different forms of the same substance, such as radioactive iodine, that are injected into the body. This allows the physician to trace the process of the substance throughout the part of the body that is being tested for disease.

A liver scan is usually ordered after blood studies and other imaging procedures have shown a liver abnormality. It is most often used to further evaluate masses or tumors. These may be benign growths in the liver, or cancer which has developed in the liver or has spread (or metastasized) from another organ.

A liver scan may also be helpful in diagnosing specific disorders, by detecting features which are characteristic of a disorder, such as **cirrhosis** of the liver. This study may also be part of the battery of tests used to evaluate potential candidates for liver transplant.

Description

This test can be performed in an outpatient setting or a hospital x-ray department. The patient usually lies down while a radioactive substance (radioactive isotope) which accumulates in the liver is injected through a vein in the arm. Scanning times may vary, depending on the specific radioisotope used. It most often begins within minutes after injection. The radionuclide scanner, sometimes called a gamma camera or scintillation camera, is positioned above the upper abdomen and may lightly touch the patient. It is important for the patient to lie quietly. Position changes and brief periods of breath holding may be required. The test usually takes approximately one hour.

A specialized liver scan used to assess blood flow is frequently used. It may be referred to as a radionuclide blood pool or volume study, a labeled red cell scintigram, or some combination of these terms. Other studies may be named for the radioisotope used. This test may also be called a liver-spleen scan.

Preparation

No physical preparation is required. A liver scan should be performed before doing any study that uses iodinated or barium-containing contrast agents, to prevent inaccurate results.

The patients should understand that there is no danger of radioactive exposure to themselves or others. Only small amounts of radionuclide are used. The total amount of radiation absorbed is often less than the dose received from ordinary x rays. The scanner does not emit any radiation, but detects and records it from the patient.

KEY TERMS

Radioisotope—A radioactive, or radiation-emitting form of an element.

Radionuclide—A substance which emits radiation that can be detected by a scanner as the substance disintegrates.

Aftercare

No special precautions are needed.

Results

A normal scan will show a liver of normal size, shape, and position.

An abnormal liver scan may result from a mass. Depending on the radioisotope and technique used, the scan may identify particular types of tumors or certain cancers. Too much radioisotope in the spleen and bones, compared to the liver, can indicate potential **hypertension** or cirrhosis. Liver diseases such as cirrhosis or hepatitis may also cause an abnormal scan, but are rarely diagnosed from the information revealed by this study alone.

Risks

Women who are pregnant or breast feeding should not have this test.

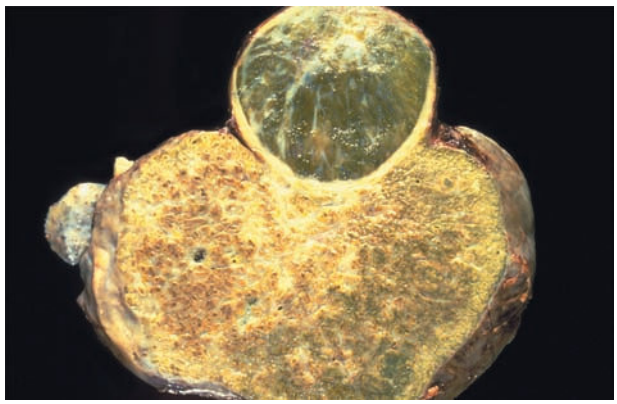
Liver transplantation

Definition

Liver transplantation is a surgery that removes a diseased liver and replaces it with a healthy donor liver.

WWW.BOOKBAZ.IR



The diseased liver of a patient ready for transplantation. *(Custom Medical Stock Photo, Inc.)*

Purpose

A liver transplant is needed when the liver's function is reduced to the point that the life of the patient is threatened.

Demographics

Approximately 6,000 liver transplants are performed each year in the United States. The number of transplants is limited by the number of donors. Compared to Caucasians, people of African, Asian, Pacific Islander, or Hispanic descent are three times more likely to suffer from end-stage **liver disease** (ESLD). Both children and adults can develop liver failure and require a transplant.

Patients with advanced heart and lung disease, who abuse drugs and alcohol, or who have multiple medical conditions are poor candidates for liver transplantation. Their ability to survive the surgery and the difficult recovery period, as well as their long-term prognosis, is hindered by their conditions. Individuals with mental health conditions that prevent them from following a complex recovery protocol may also be poor candidates for liver transplantation.

Description

The liver is the body's principle chemical factory. It receives all nutrients, drugs, and toxins absorbed into the blood from the intestines and performs the final stages of digestion, converting food into energy and replacement parts for the body. The liver also filters the blood of waste products, removes and detoxifies many poisons, and excretes many of these into the bile. It further processes other compounds for excretion by the kidneys. The liver is also an energy storage organ, converting food energy into glycogen that can be rapidly reconverted into fuel to meet energy stresses on the body.

When the liver fails to perform its functions, a transplant is necessary to save the life of the patient. Since 1963, when the first human liver transplant was performed, thousands have been performed each year. **Cirrhosis**, a disease where healthy liver cells are replaced with scar tissue, is the most common reason for liver transplantation in adults. Cirrhosis can result from chronic viral infection (**hepatitis B** or C), **alcoholism**, **fatty liver** disease (nonalcoholic steatohepatitis), autoimmune disease (**primary biliary cirrhosis**, primary sclerosing **cholangitis**), and many other causes. The most frequent reason for transplantation in children is biliary atresia—a disorder in which the ducts that carry bile out of the liver are missing or damaged.

There are many causes of liver failure that may necessitate **transplant surgery**:

- Progressive hepatitis, mostly due to infection with the hepatitis C virus, accounts for more than one-third of all liver transplants.
- Alcohol-related cirrhosis accounts for approximately 20% of transplants.
- Scarring, or abnormality of the biliary system, accounts for roughly another 20% of liver transplants.
- The remainder of transplants come from various cancers, uncommon diseases, and acute failure of the liver known as fulminant liver failure.

Fulminant liver failure most commonly happens during acute viral hepatitis, but it can also result from **mushroom poisoning** by *Amanita phalloides* and toxic reactions to overdose of some medicines, such as **acetaminophen** (Tylenol)—a commonly used **pain** reliever. A person with fuliminant liver failure has special priority (status I) for a liver transplant because of the speed of the disease and the immediate need for treatment. Many patients with chronic liver failure wait many months for a donor organ.

As the liver fails, its functions diminish. **Nutrition** suffers, toxins build up in the blood, and waste products accumulate. Scar tissue accumulates on the liver as the disease progresses. Blood flow is increasingly restricted in the portal vein, which carries blood from the stomach and abdominal organs to the liver. The resulting high blood pressure (**hypertension**) may cause swelling of and bleeding from the blood vessels in the esophagus. Toxins increase in the blood (**liver encephalopathy**), resulting in severe **jaundice** (yellowing of the skin and eyes), fluid accumulation in the

abdomen (**ascites**), and deterioration of mental function. Eventually, death occurs.

There are three types of liver transplantation methods:

- Orthotopic transplantation is the replacement of a whole diseased liver with a healthy donor liver.
- Heterotrophic transplantation is the addition of a donor liver at another site with the diseased liver left intact.
- Reduced-size liver transplantation is the replacement of a whole diseased liver with a portion of a healthy donor liver (most often performed on children).

When an orthotopic transplantation is performed, a segment of the inferior vena cava (the body's main vein returning blood to the heart) attached to the liver is taken from the donor, as well. The same parts are removed from the recipient and are replaced by connecting the inferior vena cava, the hepatic artery, the portal vein, and the bile ducts. A slight variation is the "piggyback" technique, where the recipient vena cava is left intact.

When there is a possibility that the damaged liver may recover, a heterotopic transplantation is performed. The donor liver is placed in a different site, but it still has to have the same connections. It is usually attached very close to the patient's original liver. If the original liver recovers, the donor liver will wither away. If the patient's original liver does not recover, that liver will dry up, leaving the donor in place. Heterotopic transplantation is rarely performed.

Reduced-size liver transplantation puts part of a donor liver into a patient. A liver can be divided into eight pieces—each supplied by a different set of blood vessels. If the recipient is a small child, just two of these sections can provide enough liver tissue. It is possible, therefore, to transplant one liver into at least two patients and to transplant part of a liver from a living donor and have both the donor and recipients to survive. Liver tissue grows to accommodate its job, provided that the organ is initially large enough. Patients have survived with only 15–20% of their original liver intact, assuming that the portion was healthy from the beginning.

As of 2014, the number of patients needing new livers exceeded substantially the availability of donor livers. The availability of donor organs is regulated by a national distribution system. Livers can be preserved out of the body for 10–20 hours by flushing them with cooled solutions of special chemicals and nutrients. This enables cross-country transport.

Patients who need a liver transplant are evaluated through an extensive series of blood, heart, lung, and other tests. The results of these tests are evaluated by a Liver Transplant Selection Committee made up of liver and transplant physicians, a financial counselor, and a mental health professional. Once approved, the patient is given a Model of End-stage Liver Disease (MELD) score calculated by a computer based on the test results. Sicker people receive higher scores and are placed near the top of the list. Patients who are awaiting liver transplant primarily for **liver cancer** receive artificial MELD points that then increase every three months until the patient is transplanted.

Once a donor liver has been located and the patient is in the operating room and under general **anesthesia**, the patient's heart and blood pressure are monitored. A long cut is made alongside the ribs; sometimes, an upward cut may also be made. When the liver is removed, four blood vessels that connect the liver to the rest of the body are cut and clamped shut. After getting the donor liver ready, the transplant surgeon connects these vessels to the donor vessels. A connection is made from the bile duct (a tube that drains the bile from the liver) of the donor liver to the bile duct of the liver of the patient's bile duct. In some cases, a small piece of the intestine is connected to the new donor bile duct. This connection is called Roux-en-Y. The operation usually takes between six and eight hours; another two hours is spent preparing the patient for surgery. Therefore, a patient will likely be in the operating room for 8–10 hours.

Split-liver techniques mean that a single, high-quality donor liver from a cadaver may be split for transplantation into more than one patient. Usually,

WWW.BOOKBAZ.IR

the left lateral segment (comprising about 20% of the entire liver) will go to a small child, while the larger right lobe ("trisegment," comprising about 80% of the entire liver) will go to an adult. Less commonly, a larger liver can be split in two for "full split" between two small adults. The success rate of this split-liver technique is slightly lower than with whole organs but serves more patients awaiting transplant.

Diagnosis

The liver starts to fail only when more than half of it is damaged. Thus, once a person demonstrates symptoms of liver failure, there is not much liver function left. Signs and symptoms of liver failure include:

- jaundice
- muscle wasting (loss of muscle)
- forgetfulness, confusion, or coma
- fatigue
- itching
- poor blood clotting
- buildup of fluid in the stomach (ascites)
- infections
- bleeding in the stomach

Preparation

The primary doctor, a hepatologist (liver specialist), a transplant surgeon, and other doctors will have to be consulted before a patient can be considered for a liver transplant. Before transplantation takes place, the patient must first go through a rigorous medical examination. Blood tests, consultations, and x-rays will be needed to determine if the patient is a good candidate. Other tests/procedures that may be conducted are: computed tomography (CAT or CT) scan, magnetic resonance image (MRI), **ultrasound**, routine **chest x-ray**, **endoscopy**, creatinine clearance, echocardiogram, electrocardiogram (EKG or ECG), **pulmonary function tests**, **liver biopsy**, and nutritional evaluation. A dietitian will evaluate the patient's nutritional needs and design an eating plan. A psychosocial evaluation will also be administered. Candidates who abuse drugs or alcohol in the three to six months prior to evaluation are not eligible for transplants.

Patients at risk of variceal bleeding from abnormal veins in the gastrointestinal tract may undergo sclerotherapy, rubber-band ligation, or transjugular intrahepatic portosystemic shunting (TIPS).

Once test results are reviewed and given to the liver transplant selection committee, the patient will be assessed for whether he or she is an appropriate candidate. Some patients are deemed too healthy for a transplant and will be followed and retested later if their liver gets worse. In general, patients with a MELD score of less than 15 will not benefit from liver transplant. Other patients are determined to be too sick to survive a transplant. The committee will not approve a transplant for these patients. Once a patient is approved, he or she will be placed on a waiting list for a donor liver. When placed on the waiting list, a patient will be given a score based on the results of the blood tests. The higher a patient's score, the sicker the patient is. This results in the patient earning a higher place on the waiting list. The exception is liver cancer patients, who do not need to get sicker but must wait a period of time and endure some risk of the cancer growing or spreading to the point of not being a transplant candidate.

Suitable candidates should try to ensure that they are as healthy as possible before surgery. The medical committee consults with the patient and family, if available, to explain the surgery and any potential complications. Many problems can arise during the waiting period. Medicines may be changed as needed, and blood tests are done to ensure that the patient is as healthy as possible before the transplant surgery. Psychological counseling during this period is strongly recommended, as well.

When a donor is found, the transplant team must be able to contact the patient quickly. The patient awaiting the organ must not eat or drink anything once instructed by the transplant team. On the other hand, the liver may not be good enough for transplantation, in which case the operation will be canceled, although this does not happen often.

Aftercare

Following surgery, the patient will wake up in the surgical intensive care unit (SICU). During this time, a tube may be inserted into the windpipe to facilitate breathing. It is removed when the patient is fully awake and strong enough to breathe on his or her own. There may be other tubes providing fluids, nutrients, and medications that are removed as the patient recovers. When safe to leave the SICU, the patient is moved to the transplant floor. Walking and eating will become the primary focus. **Physical therapy** may be started to help the patient become active, as it is an important part of recovery. When the patient begins to feel hungry and the bowels are working, regular food that is low in salt will be given.

A patient should expect to spend about 10–14 days in the hospital, although some stays may be shorter or longer. Before leaving the hospital, a patient will be advised of signs of infection or rejection, how to take medications and change dressings, and how to understand general health problems. Infection is a real danger, because medications have been given to suppress the body's immune system to reduce the chance of organ rejection. Before going home, doctors may conduct blood tests, ultrasounds, and x-rays to ensure that the patient is doing well.

The first three months after transplant are the most risky for acquiring infections. While it is difficult to avoid all potential risks, patients should use common sense and try to follow these precautions:

- Avoid people who are ill.
- Wash hands frequently.
- Tell the doctor if you are exposed to any disease.
- Tell the doctor if a cold sore, rash, or water blister appears on the body or spots appear in the throat or on the tongue.
- Stay out of crowds and rooms with poor circulation.
- Do not swim in lakes or community pools during the three months following transplant.
- Only eat meats that are well cooked.
- Stay away from soil and gardens during the three months following transplant.
- Take all medications as directed.
- Learn to recognize the early symptoms of infection.

To ensure that the transplant is successful and that the patient has a long and healthy life, a patient must continue to get good medical care to prevent and treat complications, keep in touch with doctors and nurses, and follow their advice. Nutrition plays a big part in the success of a liver transplant, so what a patient eats after the transplant is very important. **Obesity** and diabetes can severely impact survival after transplant.

Medications needed following liver transplantation

Successfully receiving a transplanted liver is only the beginning of a lifelong process. Patients with transplanted livers have to stay on **immunosuppressant drugs** for the rest of their lives to prevent organ rejection. Although many patients can reduce the dosage after the initial few months, virtually none can discontinue drugs altogether. For adolescent transplant recipients, post transplantation is a particularly difficult time, as they must learn to take responsibility for their own behavior and medication, as well as balance their developing sexuality in a body that has been transformed by the adverse effects of **immunosuppression**. Long-term outcome and tailoring of immunosuppression is of great importance.

Cyclosporine has long been the drug of choice in immunosuppression, as it is generally well tolerated and effective. Hypertension, nephrotoxicity (**kidney disease**), and post-transplant lymphoproliferative disease (PTLD) are some of the long-term adverse effects. Another drug called tacrolimus has improved the cosmetic adverse effects of cyclosporine, but has similar rates of hypertension and nephrotoxicity and possibly a higher rate of PTLD. Prednisone, mycopholate (cellcept), and tacrolimus are often combined with cyclosporine for better results. Newer immunosuppressive agents promise even better results. New drugs are constantly being tested to reduce donor organ rejection. Individuals should consult their transplant physician for the most recent information.

Results

For a successful transplant, good medical care is important. Patients and families must stay in touch with their medical teams, and drugs must be taken as advised to prevent infection and rejection of the new organ.

Morbidity and morality rate

Based on 2008 statistics, the 1-year, 3-year, and 5-year survival rates for patients receiving new livers were 87%, 78%, and 73%, respectively. More than 80% of children survive transplantation to adolescence and adulthood.

Infections occur in about half of transplant patients and often appear during the first week. Biliary complications are apparent in about 22% of recipient patients (and 6% of donors), and vascular complications occur in 9.8% of recipient patients. Other complications in donors include re-operation (4.5%) and death (0.2%).

In addition to the possible medical and surgical complications associated with organ transplantation surgeries, there may also be social, economic, and psychological effects. Close medical surveillance must continue for the rest of the patient's life.

Risks

The success rate of liver transplants varies among transplant centers and individual transplant surgeons.

KEY TERMS

Acetaminophen—A common pain reliever (e.g., Tylenol).

Anesthesia—A safe and effective means of alleviating pain during a medical procedure.

Ascites—A buildup of fluid in the stomach as a result of liver failure.

Bile ducts—Tubes carrying bile from the liver to the intestines.

Biliary atresia—A disease in which the ducts that carry bile out of the liver are missing or damaged; it is the most frequent reason for transplantation in children.

Biliary system—The tree of tubes that carries bile.

Cirrhosis—A disease in which healthy liver cells are killed and replaced with scar tissue. Cirrhosis is the most common reason for liver transplantation in adults and is often a result of alcoholism.

Computed tomography (CT or CAT) scan—A radiologic imaging modality that uses computer processing to generate an image of the tissue density in a "slice" as thin as 1–10 mm in thickness through the patient's body. These images are spaced at intervals of 0.5–1 cm. Cross-sectional anatomy can be reconstructed in several planes without exposing the patient to additional radiation. Also called computerized axial tomography (CAT) and computerized transaxial tomography (CTAT).

Electrocardiogram (EKG)—A graphic record showing the electrical activity of the heart.

Endoscopy—An instrument (endoscope) used to visualize a hollow organ's interior.

Hepatic artery—The blood vessel supplying arterial blood to the liver.

Heterotrophic transplantation—The addition of a donor liver at another site, while the diseased liver is left intact.

Immunosuppression—A disorder or condition where the immune response is reduced or absent.

Inferior vena cava—The biggest vein in the body, returning blood to the heart from the lower half of the body.

Interleukin-2 (IL-2)—A cytokine derived from T helper lymphocytes that causes proliferation of T-lymphocytes and activated B lymphocytes.

Jaundice—Yellowing of the skin and eyes caused by a buildup of bile or excessive breakdown of red blood cells.

Leukemia—A cancer of the white blood cells (WBCs).

Lymphoma—A cancer of lymphatic tissue.

Lymphoproliferative—An increase in the number of lymphocytes. Lymphocytes are a white blood cell (WBC) formed in lymphatic tissue throughout the body—in the lymph nodes, spleen, thymus, tonsils, Peyer patches, and sometimes in bone marrow.

Magnetic resonance imaging (MRI)—A test that provides pictures of organs and structures inside the body by using a magnetic field and pulses of radio wave energy to detect tumors, infection, and other types of tissue disease or damage, and helps to diagnose conditions that affect blood flow. The area of the body being studied is positioned inside a strong magnetic field.

Nephrotoxicity—The quality or state of being toxic to kidney cells.

Orthotopic transplantation—The replacement of a whole diseased liver with a healthy donor liver.

Portal vein—The blood vessel carrying venous blood from the abdominal organs to the liver.

Early failure of the transplant rarely occurs. Primary graft failure is apparent within one or two days. Rejection usually starts at the end of the first week. There may be problems such as bleeding of the bile duct after surgery, or blood vessels of the liver may become too narrow. The surgery itself may need revision because of narrowing, leaking, or **blood clots** at the connections. These issues may be solved with or without more surgery depending on the severity. Rejection does not usually impact the long-term graft or patient survival as long as it is caught early. Regular laboratory testing is important to detect early signs of rejection.

Infections are a constant risk while on immunosuppressive agents, because the immune system that is supposed to prevent them is necessarily damped down by drugs to prevent organ rejection. A method has not yet been devised to control rejection without hampering immune defenses against infections. Not only do ordinary infections pose a threat, but because of the impaired immunity, transplant patients are susceptible

to the same opportunistic infections (OIs) similar to those that threaten acquired immune deficiency syndrome (**AIDS**) patients—pneumocystis **pneumonia**, herpes and cytomegalovirus (CMV) infections, fungi, and a host of bacteria.

Drug reactions are also a continuing threat. Every drug used to suppress the immune system has potential side effects. Hypertension, nephrotoxicity, and PTLD are some of the long-term adverse effects with immunosuppressive drugs. Immunosuppressants also hinder the body's ability to resist cancer. Drugs used to prevent rejection increase the risk of certain cancers, such as lymphoma and skin cancers. Most types of cancer, however, are not more frequent in transplant recipients.

There is also a risk of the original disease returning. In the case of **hepatitis C**, recurrence is universal, unless it can be cured prior to the transplant. Newer **antiviral drugs** hold out promise for dealing with hepatitis, but are not yet reliable in curing the disease. In alcoholics, the urge to drink alcohol will still be a problem. Alcoholics Anonymous (AA) is the one of most effective treatments known for alcoholism. Ongoing **rehabilitation** before and after the transplant is mandatory.

Transplant recipients are at risk of high blood pressure, diabetes, high **cholesterol**, thinning of the bones, and obesity. Close medical care is needed to prevent these conditions.

Alternatives

There is no treatment that can help the liver with all of its functions; thus, when a person reaches a certain stage of liver disease, a liver transplant is the only way to save the patient's life.

Lobectomy

Definition

A lobectomy is the removal of a lobe of one of the organs, usually referring to the brain, the lung, or the liver.

Purpose

Lobectomies are usually performed to prevent the spread of cancer from one part of an organ to other

WWW.BOOKBAZ.IR

parts or to other parts of the body. Lobectomies also are performed on patients with severe seizure disorders (such as some forms of **epilepsy**) to prevent further seizures. However, there are differences in each of the three organs on which lobectomies may be performed.

Description

The brain

Each lobe of the brain performs a different function, and when part of the brain is removed, it does not grow back. However, other parts of the brain can take over some, or all, of the function of the missing part of the brain. Depending on the part of the brain removed, the effects may be quite severe, or nearly nonexistent.

The most commonly referenced brain lobectomy in the medical literature is the removal of the temporal lobe. Temporal lobectomy usually is performed to prevent debilitating seizures. Seizures are commonly caused by temporal lobe epilepsy, but can also be caused by brain tumors in the temporal lobe. Thus, lobectomy of the temporal lobe in patients with a temporal lobe tumor reduces or eliminates seizures, and has the beneficial side effect of removing the tumor mass.

The lung

Lobectomies of the lung also are called pulmonary lobectomies. Each part of the lung performs the same function: it exchanges oxygen for carbon dioxide in the blood. There are many different lobes of the lung, however, and some lobes exchange more oxygen than others. Lobes of the lung do not regenerate after they are removed. Therefore, removal of a large portion of the lung may cause a person to need oxygen or ventilator support for the rest of his or her life. However, removal of a small portion of the lung may result in very little change to the patient's quality of life. A test (a quantitative ventilation/perfusion scan, or quantitative V/Q scan) may be used before surgery to help determine how much of the lung can safely be removed.

The outcome of lung lobectomies also depends on the general health of the entire lung; **emphysema** and **smoking** would have a negative impact on the health of a patient's lung. The surgeon may perform the surgery with video assistance and special tools to decrease **pain** and speed patient recovery following surgery.

The liver

A lobectomy of the liver is also called a hepatic lobectomy. The liver plays a major role in digestion, in the transformation of food into energy, and in filtering and storing blood. It processes nutrients and drugs, produces bile, controls the level of glucose (sugar) in the blood, detoxifies blood, and regulates blood clotting. Unlike the brain and the lung, the liver may regrow, or regenerate, after part of the liver has been removed. In addition, since every part of the liver performs the same functions, the liver is the organ whose function is least likely to be severely affected by lobectomy, in the long term, because it regenerates. However, as the liver is central to the body's functions, removal of too much of the liver at once may result in **coma** or death.

Precautions

Brain lobectomies should not be performed unless the patient has been unable to control seizures through medication. Additionally, the seizures must be caused by a single, relatively small, localized part of the brain that can be resected without severe damage. Lung lobectomies should only be performed on patients with early stage non-small cell carcinoma of the lung, or as part of a combination of therapies at later stages. Since even a "complete removal" of the tumor does not result in an overwhelming survival rate after five years, other therapies also may be considered. Small cell cancer of the lung does not respond to surgical intervention. Patients with **liver disease** that is too extensive may need a liver transplant rather than a liver lobectomy. Patients with blood clotting problems, either due to chemotherapeutic agents or for other reasons, should have these problems addressed before surgery.

Preparation

Before surgery, patients should not take **aspirin** or ibuprofen for one week. Patients also should consult their physician about any blood-thinning medications such as coumadin or warfarin. The night before surgery, patients will usually be asked not to eat or drink after a certain time.

Aftercare

Each surgery offers different aftercare challenges. Patients may need to be hospitalized for some time after the operation. Patients with portions of their brain removed may require **rehabilitation** of a physical, mental, or emotional nature depending on the portion of

the brain that has been removed. Patients who have had portions of their lungs removed probably will require a tube in their chest to drain fluid, and may require a machine to help them breathe. They also may require oxygen, either on a temporary or permanent basis. Patients who have had hepatic lobectomies also may have drainage tubes, and may also have initial dietary restrictions. Physicians should be consulted for the specifics of aftercare in each individual situation.

Results

Most patients who undergo temporal lobectomy experience few or no seizures after surgery (some estimates range from about 70% to about 90% success rate). Unfortunately, lung lobectomy is not as successful. 50% of cancer patients with completely removable stage I non-small cell cancer of the lung survive five years after the procedure. If the cancer has progressed beyond this stage, or if the cancer is not completely removable, the chances for survival drop significantly. The results of liver resection vary. The possible outcomes of each surgical type should be discussed with the patient's physician. Generally, the less severe the cancer, and the less tissue that needs to be removed, the better the outcome.

Abnormal results vary from operation to operation and should be discussed thoroughly with the patient's physician before surgery. Patients who undergo temporal lobectomy may, rarely, die as a result of the operation (a complication in less than 1% of patients). Patients also may have problems with their vision, or problems with speech. Abnormal results from the removal of part of the lung could include pneumonia or blood clots (which may result in **stroke**, **heart attack**, or other problems) after the surgery. Also, a small percentage of patients undergoing lung lobectomy die during or soon after the surgery. The percentage of patients who suffer death varies from about 3–6% depending on the amount of lung tissue removed. Finally, abnormal outcomes from liver resection can include coma, death, and problems with liver function.

Risks

Specific risks vary from surgery to surgery and should be discussed with a physician. In general, any surgery requiring a general anesthetic may, uncommonly, result in death. Improperly performed brain surgery may result in permanent brain damage. Depending on the surgeon and the size of the tissue removed, patients may be at risk for some types of brain damage. As previously mentioned, patients having part of a lung removed may have difficulty breathing and may require the use of oxygen. Patients also may experience infection (**pneumonia**), or **blood clots**. Liver resection (surgery) may result in the following complications: coma, slow return of normal bowel function, and biliary leakage.

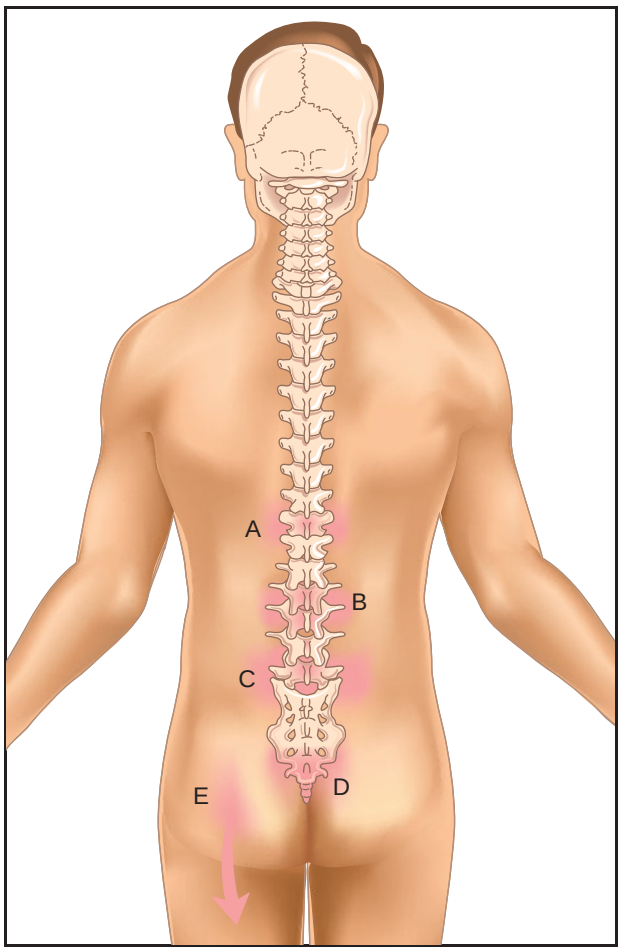
Low back pain

Definition

Low back **pain** is a common musculoskeletal symptom that may be either acute or chronic. It may be caused by a variety of diseases and disorders that affect the lumbar spine. Low back pain is often accompanied by **sciatica**, which is pain that involves the sciatic nerve and is felt in the lower back, the buttocks, and the backs of the thighs.

WWW.BOOKBAZ.IR



Sites of low back pain. Pain anywhere along the spine (A) can be caused by osteoarthritis. Pain along one or the other side of the spine may be (B) a kidney infection. Trauma to back muscles, joints, or disks (C) causes low back pain. Damage to the coccyx (D) can occur during a fall. Sciatica (E) can cause pain to run down from the back and buttocks area down a leg. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

Description

Low back pain is a symptom that affects 80% of the general United States population at some point in life with sufficient severity to cause absence from work. It is the second most common reason for visits to primary care doctors, and is estimated to cost the American economy $75 billion every year.

Low back pain may be experienced in several different ways:

- Localized. In localized pain the patient will feel soreness or discomfort when the doctor palpates, or presses on, a specific surface area of the lower back.
- Diffuse. Diffuse pain is spread over a larger area and comes from deep tissue layers.
- Radicular. The pain is caused by irritation of a nerve root. Sciatica is an example of radicular pain.
- Referred. The pain is perceived in the lower back but is caused by inflammation elsewhere—often in the kidneys or lower abdomen.

Causes and Symptoms

Acute pain

Acute pain in the lower back that does not extend to the leg is most commonly caused by a sprain or muscle tear, usually occurring within 24 hours of heavy lifting or overuse of the back muscles. The pain is usually localized, and there may be **muscle spasms** or soreness when the doctor touches the area. The patient usually feels better when resting.

Chronic pain

Chronic low back pain has several different possible causes:

MECHANICAL. Chronic strain on the muscles of the lower back may be caused by **obesity**; **pregnancy**; or job-related stooping, bending, or other stressful postures.

MALIGNANCY. Low back pain at night that is not relieved by lying down may be caused by a tumor in the cauda equina (the roots of the spinal nerves controlling sensation in and movement of the legs), or a cancer that has spread to the spine from the prostate, breasts, or lungs. The risk factors for the spread of cancer to the lower back include a history of **smoking**, sudden weight loss, and age over 50.

ANKYLOSING SPONDYLITIS. Ankylosing spondylitis is a form of arthritis that causes chronic pain in the lower back. The pain is made worse by sitting or lying down and improves when the patient gets up. It is most commonly seen in males between 16 and 35. Ankylosing spondylitis is often confused with mechanical back pain in its early stages.

HERNIATED SPINAL DISK. Disk herniation is a disorder in which a spinal disk begins to bulge outward between the vertebrae. Herniated or ruptured disks are a common cause of chronic low back pain in adults.

PSYCHOGENIC. Back pain that is out of proportion to a minor injury, or that is unusually prolonged, may be associated with a somatoform disorder or other psychiatric disturbance.

Low back pain with leg involvement

Low back pain that radiates down the leg usually indicates involvement of the sciatic nerve. The nerve can be pinched or irritated by herniated disks, tumors of the cauda equina, abscesses in the space between the spinal cord and its covering, **spinal stenosis**, and compression **fractures**. Some patients experience numbness or weakness of the legs as well as pain.

Diagnosis

The diagnosis of low back pain can be complicated. Most cases are initially evaluated by primary care physicians rather than by specialists.

Initial workup

PATIENT HISTORY. The doctor will ask the patient specific questions about the location of the pain, its characteristics, its onset, and the body positions or activities that make it better or worse. If the doctor suspects that the pain is referred from other organs, he or she will ask about a history of diabetes, peptic **ulcers**, **kidney stones**, urinary tract infections, or **heart murmurs**.

PHYSICAL EXAMINATION. The doctor will examine the patient's back and hips to check for conditions that require surgery or emergency treatment. The examination includes several tests that involve moving the patient's legs in specific positions to test for nerve root irritation or disk herniation. The flexibility of the lumbar vertebrae may be measured to rule out ankylosing spondylitis.

Imaging studies

Imaging studies are not usually performed on patients whose history and **physical examination** suggest routine muscle strain or overuse. X rays are ordered for patients whose symptoms suggest cancer, infection, inflammation, pelvic or abdominal disease, or bone fractures. MRIs are usually ordered only for patients with certain types of masses or tumors.

It is important to know that the appearance of some abnormalities on imaging studies of the lower back does not necessarily indicate that they cause the pain. Many patients have minor deformities that do not create symptoms. The doctor must compare the results of imaging studies very carefully with information from the patient's history and physical examination.

Treatment

All forms of treatment of low back pain are aimed either at symptom relief or to prevent interference with the processes of healing. None of these methods appear to speed up healing.

Acute pain

Acute back pain is treated with **nonsteroidal anti-inflammatory drugs** (NSAIDs), such as ibuprofen, **muscle relaxants**, or **aspirin**. Applications of heat or cold compresses are also helpful to most patients. If the patient has not experienced some improvement after several weeks of treatment, the doctor will reinvestigate the cause of the pain.

Chronic pain

Patients with chronic back pain are treated with a combination of medications, **physical therapy**, andoccupational or lifestyle modification. The medicationsgiven are usually NSAIDs, although patients withhypertension, kidney problems, or stomach ulcers should not take these drugs. Patients who take NSAIDs for longer than six weeks should be monitored periodically for complications.

Physical therapy for chronic low back pain usually includes regular **exercise** for fitness and flexibility, and massage or application of heat if necessary.

Lifestyle modifications include giving up smoking, weight reduction (if necessary), and evaluation of the patient's occupation or other customary activities.

Patients with herniated disks are treated surgically if the pain does not respond to medication.

Patients with chronic low back pain sometimesbenefit from **pain management** techniques, including **biofeedback**, **acupuncture**, and **chiropractic** manipulation of the spine.

Psychotherapy is recommended for patients whose back pain is associated with a somatoform, **anxiety**, or depressive disorder.

Low back pain with leg involvement

Treatment of sciatica and other disorders that involve the legs may include NSAIDs. Patients with long-standing sciatica or spinal stenosis that do not respond to NSAIDs are treated surgically. Although some doctors use cortisone injections to relieve the pain, this form of treatment is still debated.

KEY TERMS

Ankylosing spondylitis—A type of arthritis that causes gradual loss of flexibility in the spinal column. It occurs most commonly in males between 16 and 35.

Cauda equina—The roots of the spinal nerves controlling movement and sensation in the legs. These nerve roots are located in the lower spine and resemble a horse's tail (*cauda equina* in Latin).

Chiropractic—A method of treatment based on the interactions of the spine and the nervous system. Chiropractors adjust or manipulate segments of the patient's spinal column in order to relieve pain.

Lumbar spine—The segment of the human spine above the pelvis that is involved in low back pain. There are five vertebrae, or bones, in the lumbar spine.

Radicular—Pain that is caused by the root of a nerve.

Referred pain—Pain that is experienced in one part of the body but originates in another organ or area. The pain is referred because the nerves that supply the damaged organ enter the spine in the same segment as the nerves that supply the area where the pain is felt.

Sciatica—Pain caused by irritation of the sciatic nerve. Sciatica is felt in the lower back, the buttocks, and the backs of the upper legs.

Spinal stenosis—A form of sciatica that is caused by a narrowing of the spinal canal in the lumbar vertebrae. The narrowing puts pressure on the roots of the sciatic nerve.

Alternatives

A thorough differential diagnosis is important before any treatment is considered. There are times when alternative therapies are the most beneficial, and other times when more invasive treatments are needed.

Chiropractic

Chiropractic treats patients by manipulating or adjusting sections of the spine. It is one of the most popular forms of alternative treatment in the United States for relief of back pain caused by straining or lifting injuries. Some osteopathic physicians, physical therapists, and naturopathic physicians also use spinal manipulation to treat patients with low back pain.

Traditional Chinese medicine

Practitioners of **traditional Chinese medicine** treat low back pain with acupuncture, *tui na* (push-and-rub) massage, and the application of herbal poultices.

Herbal medicine

Herbal medicine can utilize a variety of antispasmodic herbs in combination to help relieve low back pain due to spasm. Lobelia (*Lobelia inflata*) and myrrh (*Commiphora molmol*) are two examples of antispasmodic herbs.

Homeopathy

Homeopathic treatment for acute back pain consists of applications of *Arnica* oil to the sore area or oral doses of *Arnica* or *Rhus toxicodendron*. *Bellis perennis* is recommended for deep muscle injuries. Other remedies may be recommended based on the symptoms presented by the patient.

Body work and yoga

Massage and the numerous other body work techniques can be very effective in treating low back pain. **Yoga**, practiced regularly and done properly, can be most useful in preventing future episodes of low back pain.

Prognosis

The prognosis for most patients with acute low back pain is excellent. About 80% of patients recover completely in 4–6 weeks. The prognosis for recovery from chronic pain depends on the underlying cause.

Prevention

Low back pain due to muscle strain can be prevented by lifestyle choices, including regular physical exercise and weight control, avoiding smoking, and learning the proper techniques for lifting and moving heavy objects. Exercises designed to strengthen the muscles of the lower back, and chairs or car seats with lumbar supports are also recommended.

Low-carbohydrate diets

Definition

Low-carbohydrate (low-carb) **diets** restrict calories from both simple or added sugars and from complex carbohydrates or starches. There are many different low-carb diets that differ in their philosophies, purposes, and restrictiveness. Most low-carb diets are defined as 15–20% of calories from carbohydrates. Very-low-carb diets are usually defined as 12% or less of calories from carbohydrates.

Description

Carbohydrates, protein, and fats are the major nutrients in food, and all are required for a healthy diet. Carbs are a major energy source, supplying the body with sugar in the form of glucose. Excess glucose is stored as glycogen in the muscles and liver. Once glycogen stores are filled, excess glucose can be stored as fat. Carbohydrates include both simple sugars—such as glucose, fructose, sucrose (table sugar), and lactose (milk sugar)—and complex carbohydrates—starches in foods such as bread, rice, potatoes, and pasta. Simple carbohydrates occur in nutritious foods such as fruits and dairy but are also added to sodas and other products with poor nutritional value. Complex carbohydrates generally take longer to digest than simple carbohydrates and so raise blood glucose levels more gradually. Whole grains are complex carbohydrates that are high in fiber, which is important for good **nutrition**. Low-carb diets replace sugar and starch with more vegetables, meat, fish, cheese, eggs, and nuts. They are usually high in protein but vary greatly in the degree and type of carbohydrate restriction and the amount and types of permitted fats.

Some low-carb diets are based on the glycemic index (GI) of different foods. GIs range from a low of 0 to a high of 100, depending on how rapidly a food raises blood sugar levels. Low-GI foods—such as spinach, asparagus, broccoli, tomatoes, grapefruit, and apples—have GIs of 55 or below and raise blood sugar levels gradually. High-fiber complex carbohydrates also have low GIs, whereas white bread and pasta have high GIs and raise blood sugar rapidly. However, GIs of foods depend on an individual's metabolism, as well as on how the food is prepared and other ingredients in a meal. The GI of even a simple carbohydrate can be lower when eaten with other foods, because the carbohydrate is absorbed more slowly and thus raises blood glucose levels more gradually. Also, fat lowers the GI.

Atkins diet

The Atkins diet or Atkins Nutritional Approach, first developed by Dr. Robert Atkins in 1972, initiated the low-carb diet trend, which peaked in 2004 as a $2.7 billion industry. The Atkins diet has four phases, beginning with a two-week, very-low-carb, high-protein, high-fat, ketogenic diet—only 20 g per day of carbs and unlimited fat and protein. The daily amount of carbohydrates equals about three cups of salad vegetables, such as lettuce, cucumbers, and celery, with unlimited butter, meat, cheese, oils, and other fats. This diet causes an initial rapid weight loss of mostly water, because utilization of liver and muscle glycogen due to drastically reduced carbohydrate intake has a strong but temporary diuretic effect. The second phase of the Atkins diet for ongoing weight loss allows 20–40 g of carbohydrates daily, which results in the burning of stored fat for energy. The pre-maintenance phase begins once the dieter is within about 10 lb. (4.5 kg) of the desired weight. One to three servings per week of high-carb foods, such as a piece of fruit or slice of whole-wheat bread, are added gradually. After reaching the desired weight, the maintenance phase allows 40–60 g of carbohydrates daily.

Paleo diets

Paleo diets—also called Paleolithic, caveman, Neanderthal, stone-age, or hunter-gatherer diets—are low-carb, high-protein, medium-fat plans designed to reproduce the diets assumed to have been eaten by

WWW.BOOKBAZ.IR

humans before the development of agriculture about 10,000 years ago. There are various paleo diets, but they all tend to be low in grains and other refined carbohydrates. The assumption is that early humans rarely, if ever, ate cereal grains, which are virtually indigestible without milling (grinding) and cooking. Some paleo diets call for eating large amounts of high-fat red meat, whereas others recommend a variety of very lean meats from free-range or grass-fed animals. A typical **paleo diet** calls for the following:

- high protein—about 29% of calories compared with 15% in a typical modern diet
- moderate fat—38% compared with 34% in a modern diet
- low-to-moderate carbohydrates—33% compared with 48% in a modern diet
- low-GI carbohydrates from fruits and vegetables but no potatoes or legumes that require cooking or processing
- healthy monounsaturated fats from canola, walnut, and olive oils
- high levels of omega-3 fatty acids
- high soluble fiber
- high amounts of essential vitamins, minerals, antioxidants, and phytochemicals
- small amounts of honey or maple syrup, but no refined sugar or other high-GI carbs
- little or no grain, saturated or trans fats, or salt
- no processed or canned foods
- no alcohol

Other low-carb diets

Other popular low-carb diets are:

- the South Beach diet, a moderately low-carb, low-GI diet
- the Zone, a high-protein, low-carb diet developed by Barry Sears
- low-carb Perricone diets
- Dr. Oz's popular diets, including a two-week rapid-weight-loss diet that is very low-carb with low-GI vegetables and small portions of protein
- the Bernstein low-carb, high-fat, calorie-restricted diet for stabilizing blood sugar in people with diabetes or insulin resistance
- the Hamptons low-carb, low-calorie diet that is similar to the Atkins but replaces high levels of saturated fats with healthy oils, monounsaturated fats from nuts and avocados, and omega-3 fatty acids from fish
- the Dukan diet, a high-protein, low-carb diet that initially completely eliminates carbohydrates and then gradually reintroduces them

Purpose

Low-carbohydrate diets, such as the Atkins diet, are very popular for rapid, substantial weight loss. Restricting carbohydrate intake to less than about 20 grams (g) daily forces the body to burn stored fat for energy. Since low-carb diets often have no restrictions on food quantities or calories and may be high in protein and fat, dieters can lose weight without suffering the hunger that often accompanies low-calorie, high-carbohydrate diets. Studies indicate that low-carb diets can help people lose weight because they tend to consume fewer calories, even though they may eat more protein and fat. Low-carb diets may work better than low-fat diets for overweight people who are just starting to diet. Low-carb diets also may help some people change their eating habits and maintain their weight loss. Finally, some people follow commercial low-carb diets because their associated products—such as bars, shakes, and prepared meals—simplify food shopping and meal preparation.

Various health claims are made for low-carb diets. The Atkins diet purports to boost energy while alleviating symptoms ranging from **fatigue**, irritability, headaches, and depression to some types of joint and muscle **pain**, high blood pressure, **heart disease**, diabetes, cancer, and metabolic syndrome. Paleo diets are based on the theory that the human body is adapted for diets followed by prehistoric ancestors during hundreds of thousands of years of human evolution, before the development of agriculture and animal husbandry. Modern hunter/gatherers rarely suffer from heart disease, **osteoporosis**, **obesity**, cancer, **rheumatoid arthritis**, or other chronic diseases until they adopt a modern Western diet. Paleo diets claim to strengthen the immune system, lower blood pressure and LDL (so-called bad) **cholesterol**, reduce food sensitivities, relieve symptoms of diabetes and arthritis, and reduce the risk of chronic diseases such as heart disease, type 2 diabetes, and cancer. Weight loss may be a secondary benefit. Paleo diets often allow some so-called open meals with loosened rules, making them easier to follow.

Various studies support some health benefits from low-carb diets. Some studies suggest benefits to those with diabetes who have trouble with processing sugar. For these individuals adherence to certain diets that limit carbohydrates may delay their need for medication. The health effects of such diets

KEY TERMS

Cholesterol—A fat-soluble steroid alcohol (sterol) found in animal fats and oils and produced in the body from saturated fats; high blood levels of low-density lipoprotein (LDL) or "bad" cholesterol increase the risk of heart disease.

Complex carbohydrates—Polysaccharides, such as starch, made up of hundreds or thousands of sugar units and found in foods such as rice, whole grains, and pasta, as well as fruits and vegetables.

Fructose—A sugar similar to glucose and found in fruit and honey.

Glucose—A monosaccharide and the form of sugar that the body assimilates and utilizes.

Glycemic index (GI)—A measure of the rate at which a carbohydrate raises the level of glucose in the blood.

Glycogen—A polysaccharide and the form in which glucose is stored in the liver and muscle.

Ketogenic diet—A diet abnormally high in fat and low in carbohydrates and protein that produces ketosis and alters the acid-base balance in the body.

Ketones—Breakdown products of fat.

Ketosis—An abnormal increase in ketones in the body, usually caused by uncontrolled diabetes.

Lactose—Milk sugar; a disaccharide comprised of glucose and galactose.

Metabolic syndrome—A syndrome characterized by at least three factors—such as high blood pressure, abdominal obesity, high triglyceride levels, low HDL ("good") cholesterol levels, and high fasting blood sugar levels and insulin resistance—that are linked to increased risk for heart disease and type 2 diabetes.

Omega-3 fatty acids—A type of polyunsaturated fatty acids that are beneficial for the heart.

Paleolithic—Human cultures of the Pleistocene epoch, from about one million to 10,000 years ago.

Simple carbohydrates—Sugar molecules of one or two units (monosaccharides and disaccharides, respectively), such as glucose, fructose, lactose, and sucrose.

Sucrose—Table sugar; a disaccharide comprised of glucose and fructose, usually derived from sugarcane or sugar beets.

Triglycerides—Neutral fats; lipids formed from glycerol and fatty acids that circulate in the blood as lipoprotein. An elevated triglyceride level is a risk factor for diabetes.

Type 2 diabetes—A condition in which the body does not properly utilize glucose due to insulin resistance or decreased insulin production; sometimes called adult-onset diabetes, although it is increasingly diagnosed in children.

depend on how high protein/low carb is defined. Some research suggests that a reduced-energy diet, providing 20–30% of total energy from protein and low in carbohydrate, could improve satiety and appetite control. This may help with weight loss and adherence to the diet in the short term.

Preparations

A physician should be consulted before people undertake any new diet, especially a low-carb diet. Patients should ask their physicians whether the diet is safe for them and whether they will need to take **vitamins** or other supplements. A physical evaluation should include blood tests for levels of cholesterol, **triglycerides**, glucose, insulin, and uric acid, and a glucose tolerance test. This step is especially important for pregnant women and for people who have had a **stroke** or have medical conditions such as heart or **kidney disease** or diabetes.

Paleo diets are generally introduced gradually in three phases. Doing so can help dieters stick with a paleo plan over the long term.

Precautions

Low-carb diets are controversial. They tend to help people lose weight quickly by limiting food choices so dieters eat less; therefore, it is fewer calories, rather than fewer carbohydrates, that are promoting weight loss, and it is very easy to gain back the weight once the diet is discontinued. Studies have found that after the first six months, low-carb diets are no more effective than other diets for weight loss, and very-low-carb diets are difficult to sustain. Many low-carb diets are not well balanced and may not be healthy and safe over the long term. They can be high in unhealthy saturated fats from meat, eggs, and dairy. Digesting protein removes **calcium** from the body and requires extra work by the kidneys. Some low-carb fad diets require eating specific

DR. ROBERT C. ATKINS (1930–2003)

(AP Images.)

Robert C. Atkins graduated from the University of Michigan in 1951 and received his medical degree from Cornell University Medical School in 1955 with a specialty in cardiology. As an internist and cardiologist, he developed the Atkins diet in the early 1970s. The diet is a ketogenic diet—a high protein, high fat, and very-low carbohydrate regimen resulting in ketosis. It emphasizes meat, cheese, and eggs, while discouraging foods such as bread, pasta, fruit, and sugar. It first came to public attention in 1972 with the publication of *Dr. Atkins' Diet Revolution*. The book quickly became a bestseller, but unlike most other fad diet books, this one remained popular. It has been reprinted many times and has sold more than 10 million copies worldwide. Atkins authored a number of other books on his diet, including *Dr. Atkins' New Diet Revolution* (1992), *Dr. Atkins' Quick and Easy New Diet Cookbook* (1997), and *The Vita-Nutrient Solution: Nature's Answer to Drugs* (1998).

Atkins saw about 60,000 patients in his more than 30 years of practice. He also appeared on numerous radio and television talk shows, had his own syndicated radio program, *Your Health Choices*, and authored the monthly newsletter *Dr. Atkins' Health Revelations*. Atkins received the World Organization of Alternative Medicine's Recognition of Achievement Award and was named the National Health Federation's Man of the Year. He directed the Atkins Center for Complementary Medicine from its founding in the early 1980s until his death in 2003. The company bearing his name continued to develop books and products that support his ideas on nutrition and dieting.

so-called super foods. The diets may lack essential nutrients and require taking a daily multivitamin and fiber supplement. Low carbohydrate diets can result in lower fecal butyrate concentrations, and this may have a negative long-term impact on colonic health. (Butyrates are important as food for cells lining the colon, and without them these cells can die.)

Some low-carb diets, such as the Atkins, require numerous expensive dietary supplements that may interact with prescription medicines such as warfarin. Furthermore, requirements for calories, fat, and other nutrients differ significantly among individuals, depending on gender, age, weight, and the presence of diseases or conditions. Pregnant or **breastfeeding** women should be especially cautious, because vitamin or mineral deficiencies could have a significant negative impact on the developing baby. Although fatty fish are a good source of **omega-3 fatty acids**, oily fish are high in calories and possibly in mercury and other toxins. Low-carb diets may not be adaptable for vegetarians and vegans and are not usually recommended for active children and teens.

Many experts do not support low-GI diets, since various factors affect the GI values of foods. The American Diabetes Association recommends carbohydrate counting, beginning with 45–60 g per meal. Portion sizes can be estimated by limiting carbs to one-fourth of the plate, with another fourth devoted to protein, such as meat or meat substitutes, and the remaining half composed of non-starchy vegetables. This is similar to the U.S. Department of Agriculture's My Plate, which recommends filling half the plate with fruits and vegetables and the remaining quarters with carbohydrates and protein.

The Atkins diet differs drastically from recommended dietary intakes. It includes fat levels that are considered unhealthy, and it is lacking in some essential vitamins and **minerals**, sufficient fiber, and possibly other nutrients that are supplied by high-carbohydrate fruits and whole grains. Many experts believe that the healthiest and most effective means to permanent weight loss is losing weight at a moderate pace through healthy eating and increased **exercise**. They recommend reducing portion sizes and, rather than

eliminating carbs, replacing refined carbohydrates with high-fiber whole grains, fruits, vegetables, and beans.

Although paleo diets may have health benefits, they are also criticized by many experts. For example, dairy and grains are important food groups that are excluded in paleo diets. Following these diets may lead to nutrient deficiencies. Dairy products are a major source of calcium needed to build and maintain bones and teeth. Calcium deficiency can cause a variety of problems including **rickets** and osteoporosis. Whole grains are an important source of dietary fiber that provides the bulk needed for a healthy digestive system. The world's food supply is based on grains, and meat—especially from free-range or grass-fed animals—is expensive and raises questions about sustainability. Large amounts of high-fat red meat may increase the risk of cardiovascular disease and are associated with increased risk for colorectal cancer. Paleo diets may not be appropriate for children, pregnant women, and people who are obese or have diabetes.

Side effects

Some people on low-carb diets experience short-term side effects, including **diarrhea**, **constipation**, **dizziness**, or sleep disturbances. Restricting carbohydrates can cause lethargy and fatigue, and people who exercise regularly may experience low energy levels and muscle fatigue. People with insulin-dependent diabetes may be at risk for **hypoglycemia** from low-carb diets. Ketosis occurs from the overproduction of ketones from fat burning when carbs are limited. Ketosis is characterized by nausea, **headache**, fatigue, and **bad breath** and, if sustained, can result in liver or kidney damage.

Reported complications from the Atkins diet include:

- ketosis
- dehydration
- electrolyte loss
- calcium depletion
- weakness
- nausea
- kidney problems

Low-density lipoproteins (LDL)

Definition

Low-density lipoprotein, or LDL, is a molecule made of lipids and protein. LDL that transports **cholesterol** to all of the cells of the body. This cholesterol-carrying combination is called LDL cholesterol (LDL-C). The amount of LDL-C in the blood is part of an individual's total cholesterol level. LDL-C is also known as "bad" cholesterol, and too much of it is a risk factor for **heart attack** and **stroke**. This is because LDL-C can cause a thick, hard substance, known as plaque, to build up on the walls of arteries, narrowing the amount of space through which the blood can flow. This is known as hardening of the arteries, or atherosclerosis. Therefore, the higher the concentration of LDL-C in the blood, the greater the risk of **heart disease**.

Description

Cholesterol is a waxy, fat-like substance that comes from two sources. One is animal-derived foods, such as meat, milk, and eggs. The other is the human liver, which produces cholesterol. Cholesterol cannot dissolve in the blood and needs lipoproteins to carry it, either: LDL or high-density lipoprotein (HDL). Cholesterol-carrying HDL (HDL-C) is considered "good" cholesterol. It removes LDL from the bloodstream and delivers it to the liver, where LDL is broken down and eliminated. For that reason, a high level of HDL is considered healthy. On the other hand, a high level of LDL cholesterol (LDL-C), which can lead to cardiovascular problems, is considered unhealthy.

Besides cholesterol, lipoproteins also transport other molecules, including phospholipids (which contain phosphates) and **triglycerides** (fats found in the blood that mainly come from the food people eat). The concentrations of LDL-C and HDL-C are both part of a patient's total cholesterol level, as is 20% of a patient's triglyceride level.

LDL Cholesterol

<70	Suggested range for people with heart or blood vessel diseases
<100	Optimal
100 - 129	Near optimal
130 - 159	Borderline high
160 - 189	High
190<	Very high

(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Risk factors

A patient may experience a too-high level of LDL-C for many reasons. People who smoke are more likely to have elevated levels of LDL-C, as are people who partake in a diet that is rich in fatty, animal-derived foods, and who do not get enough **exercise**. In addition, persons with high blood pressure, diabetes, or a family history of heart disease are also more likely to have elevated LDL-C. Some individuals develop extremely elevated LDL-C levels due to familial **hypercholesterolemia**, a genetic disorder that severely restrains their body's ability to clear cholesterol from the blood.

Demographics

The percentage of Americans who have high LDL-C has decreased significantly in recent years. According to a 2013 report by the National Center for Health Statistics (NCHS), the prevalence of high LDL-C decreased from 59 % in 1976–1980 to 42% in 1988–1994, and even farther to 33% in 2001–2004, and 27% in 2007–2010. In addition:

- For men, the percentages with high LDL-C were 65% in 1976–1980; 50% in 1988–1994; 38% in 2001–2004, and 31% in 2007–2010.
- For women, the percentages with high LDL-C were 54% in 1976–1980; 37% in 1988–1994; 28% in 2001–2004, and 24% in 2007–2010.
- For older Americans aged 65–74, the percentages with high LDL-C were 72% in 1976–1980; 55% in 1988–1994; 43% in 2001–2004, and 30% in 2007–2010.

Causes and symptoms

Some individuals have a certain genetic makeup that inhibits their cells from removing LDL-C efficiently, or directs the liver to make too much LDL-C. Lifestyle choices can also cause high LDL-C levels. People who smoke, who are obese, or who engage in an unhealthy diet (eating fatty and animal-

derived foods) are all more likely to have high LDL-C levels, when compared to individuals who don't smoke, who have a healthy diet, and who exercise regularly.

High LDL-C levels carry no symptoms, so unless patients have a cholesterol test, they will not know that they have elevated LDL-C concentrations.

Diagnosis

A blood test is used to reveal cholesterol level, which is measured in milligrams of cholesterol per deciliter of blood (mg/dL). To prepare for the test, patients are asked to fast for 12 hours and to refrain from **smoking**. Following the blood test, the sample is sent to a lab where LDL-C, HDL-C and triglyceride levels are measured. The results are reported as total blood cholesterol (a combination of HDL-C, LDL-C, and 20 percent of the triglyceride level), and typically also as the individual levels of each of the three components.

In the past, doctors used set target numbers for total cholesterol, LDL-C, HDL-C, and triglycerides, and based treatments on those numbers. They simply compared the patient's cholesterol-test numbers to guidelines that listed optimal or desired levels. If a patient' numbers were too high (or too low in the case of HDL), a doctor would recommend lifestyle changes and/or treatments to achieve the desired levels. As of 2013, however, an expert panel of the American College of Cardiology (ACC) and American Heart Association (AHA) in conjunction with the National Heart, Lung, and Blood Institute, developed new guidelines, which are discussed below.

Physicians typically recommend an initial baseline cholesterol test at age 20, with continued tests at least every five years. The frequency of testing may be increased if a test shows results of concern, or if the patient has a family history of heart disease or high cholesterol, or has other risk factors for high cholesterol, such as smoking or high blood pressure.

Treatment

If a patient's LDL level is deemed too high, the doctor may ask the patient to make one or more of the following lifestyle changes:

- quit smoking
- moderate consumption of alcoholic beverages, limiting consumption to no more than two drinks per day for men up to age 65, and to no more than one drink per day for men older than 65 and for women
- engage in regular exercise
- eat a healthy diet
- lose weight.

The doctor may also recommend prescription medications to reduce LDL-C levels, especially if lifestyle changes do not make sufficient reductions. Some of the most commonly prescribed medications are statins. Statins are a class of drugs that block the action of an enzyme that the liver uses to make cholesterol. Statins include atorvastatin (Lipitor), fluvastatin (Lescol), lovastatin (Altoprev, Mevacor), pravastatin (Pravachol), rosuvastatin (Crestor), and simvastatin (Zocor).

In developing the 2013 cholesterol-treatment guidelines, the ACC/AHA expert panel reviewed randomized clinical trials and found no evidence to support treatments to bring levels to a specific target. In response, they eliminated the target numbers for the primary and secondary prevention of atherosclerotic cardiovascular disease, and provided recommendations regarding the appropriate intensity of statin therapy required to reduce LDL cholesterol in four groups of patients:

- for those with clinical atherosclerotic cardiovascular disease, use a high-intensity statin therapy (e.g., rosuvastatin) at 20 to 40 mg, orÊatorvastatinÊat 80 mg to achieve at least a 50% reduction in LDL-C levels
- for those with LDL-C levelsÊof 190 mg/dL or greater, use a similar high-intensity statin therapy with the goal of achieving at least a 50 % reduction in LDL-C levels
- for those who are 40–75 years old, have diabetes, and have LDL-C levels of 70–189 mg/dL (but no evidence of atherosclerotic cardiovascular disease), use a moderate-intensity statin (one that lowers LDL cholesterol by 30–49%), or possibly a high-intensity statin if the patient also has a 10-year, 7.5 % or greater risk of atherosclerotic cardiovascular disease
- for those with LDL-C levels of 70–189 mg/dL and a 10-year, 7.5 % or greater risk of atherosclerotic cardiovascular disease (but without evidence of cardiovascular disease or diabetes), use a moderate- or high-intensity statin

Beyond statins, other medications are sometimes prescribed to treat high LDL-C. These include:

- bile-acid-binding resins, such as cholestyramine (Prevalite), colesevelam (Welchol), and colestipol (Colestid), which work by encouraging the liver to remove cholesterol from the blood and use it to make bile acids
- cholesterol-absorption inhibitors, such as ezetimibe (Zetia), which limit the uptake of cholesterol from the diet
- a combination (Vytorin) of statins with a cholesterol absorption inhibitor to limit both the uptake of

dietary cholesterol and the production of cholesterol by the liver

These medications, as well as statins, carry side effects, so patients should review their treatment options with their doctor. Depending on the medication prescribed, the doctor may recommend liver-function tests to ensure that the drug is not having an adverse effect on the liver. Patients may opt to make all lifestyle measures possible as a way of cutting down the dosage of medications they need to take to maintain their blood cholesterol levels.

In opting to take cholesterol-lowering drugs, patients should also discuss with their doctor whether the drugs have been shown to both lower cholesterol levels and reduce the risk of cardiovascular disease. Research, for instance, has questioned whether Zetia has had an impact on the occurrence of cardiovascular disease.

Studies is under way on additional medications. For example, research in 2014 indicated that an experimental medication, called evolocumab, may be useful in lowering cholesterol levels, but additional studies are needed to ensure its safety and efficacy.

Prognosis

Many people live long and healthy lives even though they have elevated LDL-C levels. Studies have, however, shown a definite correlation between elevated LDL-C levels and higher risk of cardiovascular disease. This results because elevated levels of LDL can cause fat, cholesterol, and other substances to accumulate and form hard plaques that can narrow the blood vessels or also rupture, which may, in turn, result in a heart attack or stroke.

Prevention

A healthy lifestyle is the best preventive tactic for low HDL.

Low sugar diet

Definition

Low-sugar **diets** are specialized **low-carbohydrate diets** the limit added sugar, including sugar from processed foods, baked goods, soft drinks, and other sweetened beverages.

Description

Sugars are carbohydrates. Low-sugar diets usually call for replacing simple and added sugars with starchy or complex carbohydrates:

- Simple sugars are monosaccharides—glucose (dextrose), galactose, and fructose—and disaccharides—sucrose (glucose plus fructose) found in cane and beet (table) sugar, honey, and corn syrup; lactose (glucose plus galactose) found in milk products; and maltose (two molecules of glucose) found in malt. One tsp of sucrose is approximately 4 g and had about 16 calories; honey has about 5.6 g of sucrose; and 1 tsp of corn syrup has 20 calories., but these taste sweeter so less tends to be used.
- High-fructose corn syrup is a sweetener produced from corn syrup that undergoes enzymatic processing to increase its fructose content and is then mixed with glucose.
- Complex carbohydrates or starches are long, complex chains of simple sugars found in foods such whole grains, pasta, rice, starchy vegetables, and legumes. Like simple sugars, they are converted to glucose (blood sugar) in the body and used for energy, but their conversion is slower. Excess glucose from both simple and complex carbohydrates is stored in the liver and muscles as glycogen and if consumed in excess can be converted to fat.
- Naturally occurring or intrinsic sugars are those that occur naturally in whole fruits (fructose), vegetables, and milk products (lactose).
- Added or extrinsic sugars are those added during food processing, cooking, or at the table.
- Total sugar is the sum of naturally occurring and added sugars in a food.

Recommendations for sugar intake vary:

- The AHA recommends limiting added sugar to no more than half of discretionary calories—no more than 100 calories (about 6 tsp or 24 g) per day for women and no more than 150 calories (9 tsp, 36 g) for men. Children should be limited to 3 tsp (12 g). This does not include naturally occurring sugars in fruits, fruit juice, vegetables, whole grains, and low-fat dairy, which are all part of a healthy diet.
- Some cities and states have proposed "sugar taxes" and the outlawing of super-sized sodas.
- The U.K. National Health Service recommends no more than 10 tsp (40 g) of added sugar daily.
- The U.K. Scientific Advisory Committee on Nutrition calls for limiting "free sugar" to 5% of daily calories. These limits apply to glucose, fructose, sucrose, honey, and syrups added to foods, as well as naturally occurring sugar in fruit juices.
- In 2014, the World Health Organization lowered its free sugar recommendation from 10% of daily calories to 5%—about 6 tsp (24 g) for adults of normal body mass index (BMI).

Although various low-carbohydrate diets for diabetes management and weight loss have been published since the 1960s, low-sugar diets gained little attention until the 1990s. The Glycemic index (GI) was introduced by David Jenkins, a Canadian physician, in 1981. The first version of the Sugar Busters

WWW.BOOKBAZ.IR

diet, based on the GI, was published in 1998, with a revised version in 2003.

The GI is based on the post-meal blood-sugar response to a particular food compared to glucose, which is set at a GI of 100. Foods are classified according to the speed at which the body converts their carbohydrates to glucose, which raises blood sugar levels. Low-GI foods are below 55 and raise blood sugar levels more slowly than high-GI foods. The highest GI foods are table sugar, white bread, white flour, white rice, and white potatoes. In general, fiber-rich foods tend to have a low GI and less effect on blood sugar. For example, grapefruit juice has a GI of 48, oatmeal is 42, and spaghetti is 41. Although increasing the fat content would have the same effect, low GI foods are not necessarily lower in calories.

Diets such as Sugar Busters eliminate most high-GI carbohydrates to lower blood sugar and insulin levels. These diets eliminate all refined sugar, honey, and molasses; white flour products including white bread, cake, bagels, crackers, and tortillas; potatoes; most forms of white rice; corn flour; and sugared soft drinks and beer. Only foods containing 3 g of sugar or less per serving are permissible on the Sugar Busters diet.

However, the GI can be confusing for dieters and has limited usefulness because there is large variation in individual blood-sugar responses to different foods. Dieticians often instruct diabetic patients to determine their own GIs for the foods they consume, based on their individual blood-sugar responses. Factors that affect blood-glucose responses to foods include:

- age
- activity levels
- the carbohydrate, protein, fat, and fiber content of particular foods
- refining or processing of foods
- cooking
- other foods in the meal
- individual digestion speeds

Since carbohydrates have the most effect on blood-glucose levels, and most foods except meat and fats/oils contain some carbohydrate, diabetic diet plans are usually based on some form of carbohydrate counting—usually grams of carbohydrate in a particular food. In general, the amount of carbohydrate has a greater impact than the type of carbohydrate on blood-glucose levels. Until the mid-1990s, people with diabetes were usually advised to replace simple sugars with complex carbohydrates. However, it is now recognized that both simple and complex carbohydrates can be part of a diabetic diet and that blood glucose can be controlled well by focusing on total grams of carbohydrate consumed during the day. People with diabetes who are not taking insulin must keep their carbohydrate intake consistent throughout the day. Those taking insulin can decide on the types and amounts of carbohydrate to eat at each meal—provided that they do not exceed their daily allowance—because they can adjust their insulin accordingly.

The allowable grams of carbohydrates per day or per meal in a diabetic diet depend on:

- weight and weight-loss goals
- physical activity, which lowers blood glucose
- insulin or diabetes medications
- age
- blood cholesterol and triglyceride levels
- other medical conditions

Sugar is the most common ingredient added to foods, and most processed foods contain added sugar. Added sugars or caloric sweeteners in processed foods are a major obstacle to low-sugar diets, since people often do not check the labels or are unaware of them. Restaurant and convenience-store foods can also have high amounts of added sugar. Soft drinks are responsible for the most added sugar in American diets, but candy, baked goods, fruit drinks, and sweetened milk, ice cream, yogurt, and grains are also major contributors. Sugar is added to bread, crackers, soups, cereals, peanut butter, cured meats, and salad dressings. High-sugar foods are those that contain more than 22.5 g total sugar per 100 g or 20% or more in the "%Daily Value (DV)" column on food labels. Low-sugar foods are 5 g or less per 100 g or 5% or less in the %DV column.

Nutrition labels do not distinguish between naturally occurring and added sugars, although all of the sugar in any product that does not contain fruit or milk-product ingredients is added sugar. In 2014, the U.S. Food and Drug Administration proposed new rules for nutrition labels that include distinguishing between total sugars and added sugars and clarifying serving sizes.

Ingredient labels list added sugars under many different names. Other labels on foods can also be confusing:

- "Sugar-Free" means less than 0.5 g sugar per serving.
- "Reduced Sugar" or "Less Sugar" means at least 25% less per serving than the traditional variety.
- "No Added Sugars" or "Without Added Sugar" means that no sugar or sugar-containing ingredients,

such as dried fruit or juice, were added during processing.

Precautions

Any diet intended for diabetes management or weight control, including low-sugar diets, should be based on accurate medical information and sound nutritional advice. The diet should be nutritionally balanced and include foods and recipes that the dieter enjoys to help with long-term compliance.

Food labels require careful reading:

- Nutrition labels list ingredients in order of decreasing amounts. People on a low-sugar diet should not consume any product with sugar as one of the top three ingredients.
- Added sugar may be listed as cane sugar, raw sugar, brown sugar, beet sugar, turbinado sugar, dextrose, sucrose, corn sweetener, high-fructose corn syrup, sorbitol, mannitol, agave nectar, cane sugar juice, honey, maltodextrin, sorghum syrup, fruit juice concentrate, or molasses.
- Soda pop and fruit juices can contain as much as 4 tbs of sugar per can/8 oz glass.
- Sugars are added to cereals, breads, catsup, soups, sauces, and other canned foods.
- A typical recommendation is to cut the usual amount of table sugar added to cereals, tea, coffee, grapefruit, and other foods by half, then by half again each subsequent week until the craving disappears. The less sweet taste becomes familiar and acceptable.
- Many cookie and pie recipes work just as well with half the amount of sugar.

Purpose

Low-sugar diets assist in the long-term management of **diabetes mellitus** and/or weight loss or weight management. Keeping blood glucose levels under tight control through diet can significantly decrease the risk of diabetes complications such as **heart disease**, **stroke**, nerve damage, and eye and **kidney disease**. Excess dietary sugar is stored as fat and may contribute to risk of **obesity** which is associated with type 2 diabetes, cardiovascular disease and some forms of cancer, and ultimately death.

Demographics

Americans have steadily increased their consumption of added sugars. In the eighteenth century, the average American consumed only 2 lb (0.9 kg) of sugar annually; by 1970, this had increased to 123 lb (56 kg); the average American now eats 152 lb (69 kg) every year—3 lb (6 cups or 1.4 kg) each week or 41 teaspoons (tsp.) every day. According to the American Heart Association (AHA), average daily caloric intake has increased by 150–300 calories in the last three decades, with 50% of that increase from beverages.

According the U.S. Centers for Disease Control and Prevention, "empty calories" from added sugars and solid fats account for 40% of daily calories in children and teens. Soda, fruit drinks, dairy and grain desserts, pizza, and whole milk account for about half of those calories. American males aged 14–19 consume the most sugar. Teens drink more sugar-sweetened soda than water, with adolescent males consuming an average of 22 oz (651 mL) and females drinking an average of 14 oz (414 mL) of full-calorie soda daily.

Preparation

Preparation for a low-sugar or any other weight-loss or diabetes diet plan requires consulting one's physician, as well as a dietitian or diabetes counselor. In addition to considering nutritional balance and any medical factors, the diet must accommodate individual food preferences and lifestyle. Children and adolescents, athletes, and anyone with type 1 or type 2 diabetes must considering timing of meals, as well as total calories, carbohydrate intake, and specific foods. A limited amount of added sugar can enhance the taste of nutritionally important foods, such as whole-grain cereals and low-fat milk or yogurt. This may be particularly important for ensuring that children obtain the nutrients they require from foods they might otherwise refuse.

Aftercare

A low-sugar or low-carbohydrate diet for diabetes or weight management is a lifelong undertaking that requires supervision by a physician or dietitian. In particular, people with diabetes require regular medical checkups, home monitoring of blood glucose levels, and consultations for dietary adjustments.

Diabetic patients rely on all members of their health care team. Nurses have a particularly important role in teaching skills necessary for managing this complex disease and educating patients about the effects of their medications. Registered dietitians and diabetes counselors are important for nutritional planning and determining the appropriate grams of carbohydrates per meals and snacks. Diabetes education is an ongoing process that may require periodic

KEY TERMS

Added sugar—Sugar that is added to foods during processing, preparation, or eating.

Agave nectar—A sweetener produced commercially in Mexico from the leaves of agave, a succulent plant with thick fleshy leaves.

Bariatric surgery—Procedures such as gastric bypass or banding surgeries for treating obesity and type 2 diabetes.

Body mass index; BMI—A measure of body fat; the ratio of weight in kilograms to the square of height in meters.

Carbohydrate—Sugars, starches, celluloses, and gums that are a major source of calories and fiber from foods.

Disaccharide—Any sugar formed when two monosaccharides are joined together and a molecule of water is removed.

Fructose—A monosaccharide found in many fruits.

Glucose—Dextrose; the monosaccharide assimilated and utilized by the body.

Glycemic index; GI—A measurement of the speed at which the body converts carbohydrates in foods to glucose in the blood. The more rapidly carbohydrates in a food are converted to glucose, the higher its GI.

Insulin—A hormone secreted by the pancreas that enables cells of the body to utilize blood glucose.

Lactose—Milk sugar; a disaccharide consisting of glucose and galactose and found in milk products.

Monosaccharide—The simplest form of sugar. Monosaccharides combine to form disaccharides and complex carbohydrates.

Sucrose—Table sugar; a disaccharide consisting of glucose and fructose.

Turbinado sugar—Sugar made from sugarcane extract that is light brown in color with large crystals; called demerara sugar in the United Kingdom.

consultation with a specialized diabetes counselor as well as participation in a diabetes support group.

Persons following a low-sugar diet for weight loss or weight management should consult their primary-care physician to ensure that such a diet is appropriate, particularly if they participate in sports or other forms of vigorous **exercise**. They may also wish to consult a registered dietitian to help them plan an individualized low-sugar diet based on the GI.

Caregivers need to ensure that people with diabetes or obesity adhere to the food choices, meal plans, calorie and carbohydrate allotments, and meal timing prescribed by their diet. "Cheating" on one's diet can have severe short-term as well as long-term consequences for someone with poorly controlled diabetes.

Results

A properly designed low-sugar diet can help promote weight loss, stabilize blood glucose levels, lower the risk of the diabetes complications, and provide satisfactory food choices. The major problem with low-sugar diets, as well as low-carbohydrate diets in general, is the difficulty most people have in sticking with them over the long-term because of their restrictiveness. Researchers at the Mayo Clinic have noted that the dropout rate for these diets is the same as those for low-fat and other restrictive diets.

The complexity of GI-based diets is a problem. Doctors at the Joslin Diabetes Center comment: "The more complex a meal plan is, the less likely people are to follow it." Furthermore, people's bodies respond differently to so-called "high" and "low" GI foods. A registered dietitian may be able to help patients determine their own individual GIs for foods based on their blood-glucose level responses to their usual meals and snacks.

There is little consensus on the merits of low-sugar diets. Studies of low-GI diets have yielded conflicting results, and these diets are sufficiently complex as to discourage many people.

Bariatric (weight-loss) surgery is sometimes recommended for severely obese patients with type 2 diabetes and BMI over 35. Blood sugar levels usually return to normal following the procedure.

Risks

There are no known health risks to following a nutritionally sound, low-sugar diet. However, fad diets for rapid weight loss may present a health risk particularly for children and adolescents with relatively high nutrient requirements.. People with diabetes are at risk for disease complications if they fail to stay within their individual **dietary guidelines**.

Athletes, particularly long-distance runners, and anyone who exercises vigorously for long periods of time require more high-GI foods that supply glucose quickly for meeting the body's energy requirements. Low-sugar diets may not be appropriate for such people who suffer from **fatigue** if sugar is not replaced with other carbohydrates, particularly in those people who are very active.

Low testosterone

Definition

Testosterone is the most important male hormone or androgen. Low testosterone or **hypogonadism** is common in older men, in whom falling testosterone levels are sometimes referred to as andropause. In marketing campaigns, low testosterone is referred to as "low T."

Demographics

Estimates of the prevalence of low testosterone vary. It is generally believed to affect about 20% of men over age 60, 30% of men over 70, and 50% of men over 80; other estimates put the prevalence at about 39% of all men over age 45. Studies that use questionnaires to identify symptoms of low testosterone indicate that less than 10% of men in their 50s and 60s are affected, whereas population-based studies have found the prevalence to be 20–30% of men in their 50s and 60s. More than 10% of men in their 70s have symptoms of low testosterone, but more than 30% have measurably low total and free testosterone levels in their blood.

Despite the wide disparity in estimates of prevalence and the relatively low percentage of older men with symptoms, the number of men receiving testosterone treatment in the United States increased almost fourfold between 2000 and 2014, to more than two million, and the number of testosterone prescriptions increased fivefold between 2001 and 2011, to 5.3 million. Sales of testosterone drugs increased from about $324 million in 2002 to about $2 billion in 2012. Similar increases have been observed in 37 other countries. Global testosterone sales increased by 90% in the five years leading up to 2014 and were expected to reach $5 billion by 2017.

Although testosterone drugs were once used only to treat serious medical conditions, they are now used primarily to treat aging-related symptoms in men who do not have low testosterone levels. In September 2014, an expert panel recommended that the U.S. Food and Drug Administration (FDA) strengthen prescribing labels to help reduce testosterone prescriptions for treating symptoms such as low energy and low libido (sex drive).

Description

Testosterone is produced by the testes under the control of the pituitary gland in the brain. It develops and maintains male characteristics, including facial, pubic, and body hair, muscle mass, bone density, sex drive, erections, and sperm production. Testosterone also affects mood.

Testosterone levels normally tend to decline as men age, and millions of men in the United States and around the world are being prescribed testosterone gels or injections. In part, this is the result of a marketing blitz initiated by drug companies in 2008. Advertisements promise that testosterone therapy will improve energy, alertness, mental sharpness, mood, muscle tone, and sexual function and satisfaction and can help with weight loss. "Awareness" campaigns, such as AbbVie's "Is It Low T?", have led to a greater than 1,800% increase in testosterone sales. The ad campaigns may be self-fulfilling, since once men start on testosterone replacement therapy (TRT), their bodies stop producing the hormone, and if they quit TRT, they may indeed experience symptoms of low testosterone.

Some studies have suggested that testosterone therapy decreases cardiovascular problems, including heart attacks, **stroke**, and death from **heart disease**. However, other studies, including a widely reported 2013 study, found that testosterone treatments may increase cardiac risks. The Testosterone in Older Men study was halted early, after only three years, because of results indicating that high-dose testosterone therapy increased the incidence of heart problems, including heart attacks.

Risk factors

Advancing age is a major risk factor for low testosterone. In addition, low testosterone affects:

- about 40% of men with high blood pressure or high cholesterol levels
- about 50% of men with diabetes or obesity
- 30% of men with HIV and 50% of men with AIDS
- almost 75% of men with a history of chronic opioid use

Causes and symptoms

Causes

Low testosterone can result from problems with either the testicles or the pituitary gland and the brain, although in many cases the cause is unknown. Typical causes include:

- some medications, including opiate painkillers
- chronic diseases, including obesity, type 2 diabetes, liver or kidney disease, and HIV/AIDS

- injury to the testicles, such as trauma, infection, or castration
- radiation or chemotherapy for treating cancer
- hormone disorders, such as pituitary diseases or tumors or high levels of prolactin
- genetic diseases, such as Klinefelter syndrome, hemochromatosis, Kallman syndrome, Prader-Willi syndrome, and myatonic dystrophy

Symptoms

Symptoms of low testosterone vary with the individual. Symptoms tend to be vague and associated with symptoms of **aging**. Immediate symptoms of low testosterone can include:

- decreased sex drive and sexual activity
- poor erectile function, including fewer and weaker erections
- low sperm count
- enlarged breasts

Long-term symptoms of low testosterone include:

- loss of body hair
- loss of muscle mass and strength
- lack of energy
- fatigue
- increased body fat
- loss of bone calcium and weakened bones (osteoporosis)
- mood changes, grumpiness, irritability, and depression
- smaller testes
- low-iron anemia

Diagnosis

Examination

The doctor takes a medical history that includes symptoms, prescription and nonprescription drug use, sexual problems, and any major life changes. The physical exam includes body hair, size of the penis and breasts, size and consistency of the testes and scrotum, and possibly any loss of side vision, which could indicate a pituitary tumor. A primary-care doctor may refer the patient to an endocrinologist. The Endocrine Society's Clinical Practice Guidelines recommend a diagnosis of low testosterone only in men with consistent symptoms and laboratory test results that clearly show low testosterone levels.

Tests

Testosterone levels are measured with blood tests. The normal range is typically 300–1,000 nanograms per deciliter (ng/dL) of blood, depending on the laboratory. Blood should be drawn for the test in the early morning, 7–11 AM, because levels vary over the course of the day and are usually highest in the morning, although a 2014 study reported that this variation only occurs in younger men. Low testosterone should be confirmed with a second test on another day. Pituitary gland hormones may also be tested. A **prostate cancer** screening test for prostate-specific antigen (PSA) and a **hematocrit** to measure red blood cells will probably also be performed.

KEY TERMS

Androgens—Male sex hormones, especially testosterone.

Andropause—A gradual, highly variable decline in testosterone and other male hormones and associated symptoms; occurring during and after middle age.

Hematocrit—The separation of red blood cells from plasma to determine their percent volume in whole blood—normally 42–52% in males.

Hypogonadism—Functional incompetence of the male gonads, with impaired production of hormones and germ cells.

Opiate—A drug containing or derived from opium—such as codeine, morphine, or heroin—that alleviates pain and induces sleep.

Osteoporosis—A disease characterized by low bone mass and structural deterioration of bone tissue, leading to fragile bones.

Pituitary gland—A small endocrine organ in the brain that produces various hormones that control and regulate other endocrine organs; the pituitary affects most basic bodily functions, including growth and development.

Prolactin—A hormone produced by the pituitary gland.

Prostate—The walnut–shaped gland that surrounds the urethra at the neck of the bladder in males and supplies fluid for semen.

Scrotum—The external sac that contains the testes.

Testes—The paired, hormone- and sperm-producing male reproductive glands that descend into the scrotum.

Testicles—The testes and their enclosing structures.

Testosterone replacement therapy; TRT—Treatment for low testosterone levels.

WWW.BOOKBAZ.IR

Treatment

Medical conditions, including cardiovascular disease and other factors, can cause **erectile dysfunction** or other symptoms of low testosterone that may require treatment.

Drugs

There are various types of TRT, although not all are available in the United States. The choice depends on the patient's preferences, tolerance for the drug, and the cost. Testosterone is available as:

- skin gels
- skin patches
- injections
- tablets that stick onto the gums (oral inserts)
- long-acting pellets inserted under the skin
- an underarm roll-on
- pills

In the United States, about 70% of men are treated with a gel that is rubbed on the shoulders or upper arms after showering. About 17% of patients are given testosterone injections, and 10% have testosterone patches. Only about 3% of patients are treated with other forms, such as oral testosterone or implantable pellets. In September 2014, an FDA advisory committee rejected approval of a new oral testosterone-replacement drug called Rextoro.

The U.S. Institute of Medicine has long maintained that TRT for low testosterone is an "off-label" use, and the FDA stated in 2014 that TRT is only approved for treating hormonal problems caused by medical conditions. TRT should never be used for non-medical purposes, such as bodybuilding, performance enhancement, or anti-aging treatment. Side effects of TRT can include:

- acne
- breast swelling, tenderness, or soreness
- high red-blood-cell count that could increase the risk of blood clots
- decreased testicle size
- prostate enlargement or an increase in enlargement caused by benign prostatic hyperplasia, which may cause urinary symptoms
- infertility
- rarely, feet or ankle swelling or water retention, especially in men with kidney, liver, or heart problems
- rarely, breathing difficulties while asleep (apnea)

Men on TRT should have regular checkups, blood tests for testosterone levels and PSA, and a hematocrit. Men with known or suspected prostate cancer or **breast cancer** should not receive TRT. Although as of 2014, studies have not shown TRT to increase the risk of prostate cancer, it is recommended that African American men, men over 40 with close relatives diagnosed with prostate cancer, and all men over age 50 be monitored for prostate cancer while on TRT. It remains unclear how TRT affects the risk of **heart attack**; however, several studies have indicated that TRT increases the risk of heart attack in older men and in middle-aged men with a history of heart disease.

Alternatives

There are various methods for increasing energy levels and sex drive without the use of testosterone or other drugs. Typical suggestions include:

- a balanced nutritious diet
- snacking on foods containing fiber and protein between meals
- regular exercise
- taking a walk when feeling tired
- pacing oneself by spreading out activities throughout the day
- good sleep habits
- addressing psychological and relationship issues that may be affecting one's sex life

Prognosis

TRT promotes normal sexual development and the restoration of male appearance and sexual function in men with low testosterone due to conditions such as undescended testicles, genetic abnormalities, **trauma**, or **chemotherapy**. For such men, TRT improves sexual desire, erectile function, body hair growth, bone mineral density, muscle mass, sleep, mood, and energy and decreases body fat and the risk of bone **fractures**. For other men, however, the proven benefits of TRT are small increases in lean body mass and libido or sexual satisfaction. The effects of TRT on weight, strength, energy, irritability, and depression are less clear. TRT will not improve health if testosterone levels are normal, and it may decrease sperm count and fertility or cause other health problems. TRT is a lifelong treatment for a chronic condition, since stopping the treatment will cause testosterone levels to decline. Men who stop TRT often notice a very large difference.

Studies of TRT have had conflicting results. A study published in 2014 of 8,700 older military veterans with low testosterone, most of whom had risk factors for heart problems or history of heart disease, reported an approximately 30% higher risk of heart attack, stroke, or death in the men on TRT. The researchers suggested that TRT might increase the risk for heart attack or stroke by promoting blood clot formation. Another study linked TRT to increased heart attack risk in both younger and older men with preexisting heart disease. However, an earlier study of veterans reported decreased mortality in those taking testosterone, even in men with preexisting heart disease. As of 2014, an ongoing study of men aged 65 and older with low testosterone was examining the effects of TRT on walking ability, **fatigue**, sexual function, verbal memory, hemoglobin levels, and buildup of plaque in the arteries.

Prevention

There may be no way to prevent declining testosterone levels that normally accompany aging. Various alternatives to TRT, including lifestyle changes, may lessen the effects of lowered testosterone.

Lower esophageal ring

Definition

Lower esophageal ring is a condition in which there is a ring of tissue inside the lower part of the esophagus (the tube connecting the throat with the stomach). This tissue causes narrowing and partial blockage of the esophagus. Lower esophageal ring can also refer to the ring itself.

Description

Lower esophageal ring (also called Schatzki's ring and B-ring) affects about 10–14% of the population. Normally, the lower part of the esophagus, near where the esophagus meets the stomach, has an inside diameter of 1.5–2 inches. The diameter of this part of the esophagus is less when lower esophageal ring is present, and diameters as small as one-eighth inch have been seen. When the inside diameter is less than about three-fourths of an inch, intermittent difficulty with swallowing can result. About 96% of people with lower esophageal ring have no symptoms.

Causes and symptoms

Lower esophageal ring seems to result from infoldings of tissue near the bottom of the esophagus, but the underlying cause is unknown. Although some specialists speculate they are due to a congenital defect, most people do not develop symptoms until they reach their forties or later. Although lower esophageal ring is generally associated with **hiatal hernia**, and sometimes with **heartburn**, the cause/effect relationship is unclear.

Intermittent difficulty swallowing solid food is the primary symptom of this condition. The degree of difficulty in swallowing is directly related to the degree the esophagus is narrowed. Certain foods, especially tough or fibrous foods like meat, are more likely to cause swallowing difficulties.

Diagnosis

Gastroenterologists and internists are best equipped to diagnose and treat lower esophageal ring. The diagnosis is based on the patient's history of swallowing difficulties and a barium x ray of the upper gastrointestinal tract. For a barium x ray, the patient swallows a liquid containing barium, a substance that is opaque to x rays. Subsequent x-ray photography reveals the shape of the esophagus and any narrow regions present.

The presence of a lower esophageal ring can also be shown with a test called an esophagoscopy. This procedure visualizes the inside of the esophagus with an inserted, thin, flexible tube. However, this test is less sensitive for lower esophageal ring and costs about five times as much as barium x ray. However, if the findings of a barium x ray are not definitive, esophagoscopy should be done. Biopsies can then be done on questionable areas.

KEY TERMS

Bougie—A mercury-filled dilator in the shape of a cylinder or tapered cylinder. Bougies come in a range of different sizes.

Bougienage—The procedure of dilating tubal organs, like the esophagus, with a bougie or bougies.

Congenital—Existing at birth.

Dysphagia—Difficulty swallowing.

Esophagoscopy (also esophagoendoscopy)—Examination of the inside of the esophagus using a flexible tube that transmits video images.

Esophagus—The tube connecting the throat to the stomach, which is about ten inches long in adults. It is coated with mucus and surrounded by muscles, and pushes food to the stomach by sequential waves of contraction. It functions to transport food from the throat to the stomach and to keep the contents of the stomach in the stomach.

Heartburn—A burning sensation in the chest that can extend to the neck, throat, and face, caused by the movement of stomach acid into the esophagus.

Hiatal hernia—A condition where part of the stomach extends through the diaphragm into the chest cavity.

Treatment

Dietary change

Swallowing difficulties due to lower esophageal ring can often be relieved by chewing food more thoroughly. Soft foods and liquids may also be recommended.

Dilation

Lower esophageal rings can be corrected by passing a bougie (a cylindrical, mercury-filled dilator) through

the esophagus. This procedure, called bougienage, is effective most of the time, but may need to be repeated every few years. Complications and adverse reactions are extremely rare.

Surgery

If bougienage is unsuccessful, lower esophageal ring tissue can be surgically removed.

Prognosis

The probability of a favorable outcome is high. Swallowing difficulties can be alleviated in almost every case, and the rate of complications from bougienage or surgery is less than 1%.

Prevention

Since the cause of lower esophageal ring is not known, there are no definitive preventive measures. Nevertheless, anyone with lower esophageal ring who also suffers from heartburn would be wise to prevent or treat the heartburn. It is possible that the stomach acid in the esophagus associated with heartburn contributes to esophageal ring.

Lumbar puncture

Definition

Lumbar puncture (LP) is the technique of using a needle to withdraw cerebrospinal fluid (CSF) from the spinal canal. CSF is the clear, watery liquid that protects the central nervous system from injury and cushions it from the surrounding bone structure. It contains a variety of substances, particularly glucose (sugar), protein, and white blood cells from the immune system.

Purpose

Lumbar puncture, or spinal tap, is used to diagnose some malignancies, such as certain types of brain cancer and leukemia, as well as other medical conditions that affect the central nervous system. It is sometimes used to assess patients with certain psychiatric symptoms and conditions.

It is also used for injecting **chemotherapy** directly into the CSF. This type of treatment is called intrathecal therapy. Other medical conditions diagnosed with lumbar puncture include:

- viral and bacterial meningitis
- syphilis, a sexually transmitted disease
- bleeding (hemorrhaging) around the brain and spinal cord
- multiple sclerosis, a disease that affects the myelin coating of the nerve fibers of the brain and spinal cord
- Guillain-Barré syndrome, an inflammation of the nerves

Precautions

In some circumstances, a lumbar puncture to withdraw a small amount of CSF for analysis may lead to serious complications. Lumbar puncture should be performed only with extreme caution, and only if the benefits are thought to outweigh the risks, in certain conditions. For example, in people who have blood clotting (coagulation) or bleeding disorders or who are on anticoagulant treatment, lumbar puncture can cause bleeding that can compress the spinal cord. The term for this condition is spinal **subdural hematoma**, and it is a rare complication. However, it is of concern to some cancer patients whose low platelet counts (**thrombocytopenia**) make them more susceptible to bleeding. In some cases, these patients are given a platelet **transfusion** prior to lumbar puncture, but this procedure is still

WWW.BOOKBAZ.IR

under investigation. A four-year study, supported in part by the National Cancer Institute, researched the risk of lumbar puncture on children with acute lymphoblastic leukemia (ALL). No serious lumbar puncture complications were observed in this study of over 5,000 children.

Lumbar puncture has been shown to be less precise than some other methods in monitoring intracranial fluid pressure. A transducer provides more accurate information about changes in the flow of blood and cerebrospinal fluid within the brain.

A traumatic lumbar puncture (TLP) occurs when a blood vessel is inadvertently ruptured during the procedure. If this happens as part of a diagnostic leukemia workup, there is the potential of contaminating the CSF specimen that has been removed with leukemia cells, causing a false positive test result.

If there is a large **brain tumor** or other mass, removal of CSF can cause pressure shifts within the brain (herniation), causing compression of the brain stem and other vital structures, and leading to irreversible brain damage or death. These problems are easily avoided by checking blood coagulation through a blood test and by doing a computed tomography scan (CT) or **magnetic resonance imaging** (MRI) scan before attempting the lumbar puncture. In addition, a lumbar puncture procedure should never be performed at the site of a localized skin infection on the lower back because the infection may be introduced into the CSF and may spread to the brain or spinal cord.

KEY TERMS

Acute lymphoblastic leukemia (ALL)—A type of leukemia, also called acute lymphocytic leukemia, primarily in children, affecting lymphocytes.

Encephalitis—An inflammation or infection of the brain and spinal cord caused by a virus or as a complication of another infection.

Guillain-Barré syndrome—An inflammation involving nerves that affects the extremities. The inflammation may spread to the face, arms, and chest.

Immune system—Protects the body against infection.

Intrathecal therapy—Injecting chemotherapy directly into the CSF using lumbar puncture.

Manometer—A device used to measure fluid pressure.

Meningitis—An infection or inflammation of the membranes or tissues that cover the brain and spinal cord, and caused by bacteria or a virus.

Multiple sclerosis—A disease that destroys the covering (myelin sheath) of nerve fibers of the brain and spinal cord.

Spinal canal—The cavity or hollow space within the spine that contains cerebrospinal fluid.

Thrombocytopenia—Reduced platelet levels.

Vertebrae—The bones of the spinal column. There are 33 along the spine, with five (called L1–L5) making up the lower lumbar region.

Description

In a lumbar puncture, the area of the spinal column used to obtain the CSF sample is in the lumbar spine, or lower section of the back. In rare instances, such as a spinal fluid blockage in the middle of the back, a doctor may perform a spinal tap in the neck. The lower lumbar spine (usually between the vertebrae known as L4–5) is preferable because the spinal cord stops near L2, and a needle introduced below this level will miss the spinal cord and encounter only nerve roots, which are easily pushed aside.

A lumbar puncture takes about 15–30 minutes. Patients can undergo the test in a doctor's office, laboratory, or outpatient hospital setting. Sometimes it requires an inpatient hospital stay. If the patient has severe **osteoarthritis** of the spine, is extremely uncooperative, or obese, it may be necessary to introduce the spinal needle using x-ray guidance.

In order to get an accurate sample of cerebrospinal fluid, it is critical that a patient is in the proper position. The spine must be curved to allow as much space as possible between the lower vertebrae, or bones of the back, for the doctor to insert a lumbar puncture needle between the vertebrae and withdraw a small amount of fluid. The most common position is for the patient to lie on his or her side with the back at the edge of the exam table, head and chin bent down, knees drawn up to the chest, and arms clasped around the knees. (Small infants and people who are obese may need to curve their spines in a sitting position.) People should talk to their doctors if they have any questions about their position because it is important to be comfortable and to remain still during the entire procedure. In fact, the doctor will explain the procedure to the patient (or guardian) so that the patient can agree in writing to have it done (informed consent). If the patient is anxious or uncooperative, a short-acting sedative may be given.

During a lumbar puncture, the doctor drapes the back with a sterile covering that has an opening over the puncture site and cleans the skin surface with an antiseptic solution. Patients receive a local anesthetic to minimize any **pain** in the lower back.

The doctor inserts a thin hollow needle in the space between two vertebrae of the lower back and slowly advances it through ligamentous tissues toward the spine. A steady flow of clear cerebrospinal fluid, normally the color of water, will begin to fill the needle as soon as it enters the spinal canal. The doctor measures the cerebrospinal fluid pressure with a special instrument called a manometer and withdraws several vials of fluid for laboratory analysis. The amount of fluid collected depends on the type and number of tests needed to diagnose a particular medical disorder.

In some cases, the doctor must remove and reposition the needle. This occurs when there is not an even flow of fluid, the needle hits bone or a blood vessel, or the patient reports sharp, unusual pain.

Preparation

Patients can go about their normal activities before a lumbar puncture. Experts recommend that patients relax before the procedure to release any muscle tension, since the lumbar puncture needle must pass through muscle tissue before it reaches the spinal canal. A patient's level of relaxation before and during the procedure plays a critical role in the test's success. Relaxation may be difficult for those patients who face frequent lumbar punctures, such as children with leukemia. In these cases, it is especially important for the child to receive psychological support before and after each procedure. It may be helpful to praise a child who remained still and quiet during the procedure, and to remind the child of his or her good behavior before the next lumbar puncture.

Aftercare

After the procedure, the doctor covers the site of the puncture with a sterile bandage. Patients must avoid sitting or standing and remain lying down for as long as six hours after the lumbar puncture. They should also drink plenty of fluids to help prevent lumbar puncture **headache**, which is discussed in the next section.

Results

Normal CSF is clear and colorless. It may be straw or yellow–colored if there is excess protein, which may occur with cancer or inflammation. It may be cloudy in infections; blood–tinged if there was recent bleeding; or yellow to brown (xanthochromic) if caused by an older instance of bleeding.

A series of laboratory tests analyze the CSF for a variety of substances to rule out cancer or other medical disorders of the central nervous system. The following are normal values for commonly tested substances:

- CSF pressure: 50–180 mmH_2O
- Glucose: 40–85 mg/dL
- Protein: 15–50 mg/dL
- Leukocytes (white blood cells): total less than 5 per mL
- Lymphocytes (specific type of white blood cell): 60–70%
- Monocytes (a kind of white blood cell): 30–50%
- Neutrophils (another kind of white blood cell): none

Normally, there are no red blood cells in the CSF unless the needle passes though a blood vessel on route to the CSF. If this is the case, there should be more red blood cells in the first tube collected than in the last.

Abnormal

A lumbar puncture is sometimes used as part of a diagnostic cancer workup. Abnormal test result values in the pressure or any of the substances found in the cerebrospinal fluid may suggest a number of medical problems including a tumor or spinal cord obstruction; hemorrhaging or bleeding in the central nervous system; infection from bacterial, viral, or fungal microorganisms; or an inflammation of the nerves. If there is a tumor in the meninges (membranes around the brain and spinal cord), the CSF may have higher protein levels, lower glucose levels, and a mild increase in lymphocytes (pleocytosis). It is important for patients to review the results of a **cerebrospinal fluid analysis** with their doctor and to discuss any treatment plans.

Risks

The most common side effect of lumbar puncture is a headache. This problem occurs in 10–20% of adult patients and in up to 40% of children. It is caused by decreased CSF pressure related to a small leak of CSF through the puncture site. These headaches usually are a dull pain, although some people report a throbbing sensation. A stiff neck and nausea may accompany the headache. A lumbar puncture headache typically begins within a few hours to two days after the procedure and usually persists a few days, although it can last several weeks or months.

WWW.BOOKBAZ.IR

In some cases, the headache can be prevented by lying flat for an hour after the lumbar puncture, and taking in more fluids for 24 hours after the procedure. Since an upright position worsens the pain, lying flat also helps control the pain, along with prescription or non–prescription pain relief medication, preferably one containing **caffeine**. In rare cases, the puncture site leak is "patched" using the patient's own blood. People may also experience back pain. Headaches and backaches appear to be more common in adolescents than in younger children, and more common in girls than in boys.

Patients who receive **anticancer drugs** through lumbar puncture sometimes have **nausea and vomiting**. Intrathecal methotrexate can cause mouth sores. Some of these symptoms may be relieved by antinausea drugs prescribed by the physician.

In a very few cases, lumbar puncture in infants can lead to such complications as paraplegia. These complications are associated with the smaller size of the infant's central nervous system and increased difficulty in avoiding certain parts of the spinal cord when performing an LP.

People should talk to their doctors about complications from a lumbar puncture. In most cases, this procedure is safe and effective. Some patients experience pain, difficulty urinating, infection, or leakage of cerebrospinal fluid from the puncture site after the procedure.

Lumpectomy

Definition

Lumpectomy is a type of surgery for **breast cancer**. It is considered "breast-conserving" surgery because only the malignant tumor and a surrounding margin of normal breast tissue are removed. Lymph nodes in the armpit (axilla) may also be removed. This procedure is also called lymph node dissection.

Purpose

Lumpectomy is a surgical treatment for newly diagnosed breast cancer. It is estimated that at least 50% of women with breast cancer are good candidates for this procedure. The location, size, and type of tumor are of primary importance when considering breast cancer surgery options. The size of the breast is another factor the surgeon considers when recommending surgery. The patient's psychological outlook, as well as lifestyle and preferences, should also be taken into account when treatment decisions are being made.

The extent and severity of a cancer is evaluated, or "staged," according to a fairly complex system. Staging considers the size of the tumor and whether the cancer has spread (metastasized) to adjacent tissues, such as the chest wall, the lymph nodes, and/or to distant parts of the body. Women with early stage breast cancers are usually better candidates for lumpectomy. In most cases, a course of **radiation therapy** after surgery is part of the treatment. **Chemotherapy** or hormone treatment may also be prescribed.

In some instances, women with later stage breast cancer may be able to have lumpectomies. Chemotherapy may be administered before surgery to decrease tumor size and the chance of metastasis in selected cases.

Contraindications to lumpectomy

There are a number of factors that may prevent or prohibit a breast cancer patient from having a lumpectomy. The tumor itself may be too large or located in an area where it would be difficult to remove with good cosmetic results. Sometimes several areas of cancer are found in one breast, so the tumor cannot be removed as a single lump. A cancer that has already attached itself to nearby structures, such as the skin or the chest wall, needs more extensive surgery.

Certain medical or physical circumstances may also eliminate lumpectomy as a treatment option. Sometimes lumpectomy may be attempted, but the

KEY TERMS

Axillary lymph node—Lymph nodes under the arm.

Lymph node—A small mass of tissue in the form of a knot or protuberance. They are the primary source of lymph fluid, which serves in the body's defense by removing toxic fluids and bacteria.

Quadrantectomy—Removal of a quadrant, or about a quarter of the breast.

surgeon is unable to remove the tumor with a sufficient amount of surrounding normal tissue. This may be termed "persistently positive margins," or "lack of clear margins." Lumpectomy is suitable for women who have had previous lumpectomies and have a recurrence of breast cancer.

Because of the need for radiation therapy after lumpectomy, this surgery may be medically unacceptable. A breast cancer discovered during **pregnancy** is not amenable to lumpectomy because radiation therapy is part of the treatment. Radiation therapy cannot be administered to pregnant women because it may injure the fetus. If, however, delivery would be completed prior to the need for radiation, pregnant women may undergo lumpectomy. A woman who has already had therapeutic radiation to the chest area for other reasons cannot undergo additional exposure for breast cancer therapy.

The need for radiation therapy may also be a barrier due to nonmedical concerns. Some women simply fear this type of treatment and choose more extensive surgery so that radiation will not be required. The commitment of time, usually five days a week for six weeks, may not be acceptable for others. This may be due to financial, personal, or job-related constraints. Finally, in geographically isolated areas, a course of radiation therapy may require lengthy travel and perhaps unacceptable amounts of time away from family and other responsibilities.

Demographics

The American Cancer Society estimated that in 2013, 232,340 new cases of invasive breast cancer were diagnosed in women the United States, with 39,620 deaths. Approximately one in eight women will develop breast cancer at some point in her life. The risk of developing breast cancer increases with age: women aged 30 to 40 have a one in 252 chance of developing breast cancer; women aged 40 to 50 have a one in 68 chance; women aged 50 to 60 have a one in 35 chance; and women aged 60 to 70 have a one in 27 chance—and these statistics do not even account for genetic and environmental factors.

Description

Lumpectomy is usually performed by a general surgeon or surgical oncologist. Radiation therapy is administered by a radiation oncologist, and chemotherapy by a medical oncologist. The procedure is frequently done in a hospital setting (especially if lymph nodes are to be removed at the same time), but specialized outpatient facilities are sometimes preferred.

Any amount of tissue, from 1%–50% of the breast, may be removed and called a lumpectomy. Breast conservation surgery is a frequently used synonym for lumpectomy. Partial **mastectomy**, **quadrantectomy**, segmental excision, wide excision, and tylectomy are other, less commonly used names for this procedure.

The surgery is usually done while the patient is under general anesthetic. Local anesthetic with additional **sedation** may be used for some patients. The tumor and surrounding margin of tissue is removed and sent to a pathologist for examination. The surgical site is then closed. Newer techniques may use **magnetic resonance imaging** guidance to more accurately identify the breast tissue to be removed. Additionally, laser instruments may be used to perform the actual lumpectomy.

If axillary lymph nodes were not removed before, a second incision may be made in the armpit. The fat pad that contains lymph nodes is removed from this area and is also sent to the pathologist for analysis. This portion of the procedure is called an axillary lymph node dissection; it is critical for determining the stage of the cancer. Typically, 10 to 15 nodes are removed, but the number may vary. A newer alternative to axillary lymph node dissection involves removal of only one lymph node. This technique, called sentinel node biopsy, samples just the first lymph node to which the breast tissue drains. If the sentinel node is negative, it is likely that no cancer has spread to more distant lymph nodes. If the sentinel node is positive, then the surgeon may have to proceed with an axillary lymph node dissection. Surgical drains may be left in place in either location to prevent fluid accumulation. The surgery may last from one to three hours.

WWW.BOOKBAZ.IR

Preparation

Routine preoperative preparations, such as having nothing to eat or drink the night before surgery, are typically ordered for a lumpectomy. Information about expected outcomes and potential complications is also part of preparation for lumpectomy, as it is for any surgical procedure. It is especially important that women know about any side effects they might experience after the operation so that they are not misinterpreted as signs of further cancer or poor healing.

If the tumor is not able to be felt (not palpable), a preoperative localization procedure is needed. A fine wire, or other device, is placed at the tumor site, using x-ray or **ultrasound** for guidance. This is usually done in the **radiology** department of a hospital. The woman is most often sitting up and awake, although some sedation may be administered.

Aftercare

The patient may stay in the hospital one or two days, or return home the same day. This generally depends on the extent of the surgery, the medical condition of the patient, and physician and patient preferences. A woman usually goes home with a small bandage. The inner part of the surgical site usually has dissolvable stitches. The skin may be sutured or stitched, or the skin edges may be held together with Steri-Strips™, which are special thin, clear pieces of tape.

After a lumpectomy, patients are usually cautioned against lifting anything that weighs over five pounds for several days. Other activities may be restricted (especially if the axillary lymph nodes were removed) according to individual needs. **Pain** is often enough to limit inappropriate motion. Women are often instructed to wear a well-fitting support bra both day and night for approximately one week after surgery.

Pain is usually well controlled with prescribed medication. If it is not, the patient should contact the surgeon, as severe pain may be a sign of a complication that needs medical attention. A return visit to the surgeon is normally scheduled approximately ten days to two weeks after the operation.

Radiation therapy is usually started as soon as possible after lumpectomy. Other additional treatments, such as chemotherapy or hormone therapy, may also be prescribed. The timing of these is specific to each individual patient.

Results

When lumpectomy is performed, it is anticipated that it will be the definitive surgical treatment for breast cancer. Other forms of therapy, especially radiation, are often prescribed as part of the total treatment plan. The expected outcome is no recurrence of the breast cancer.

Morbidity and mortality rates

The outcome of breast cancer is very dependent on the stage at the time of diagnosis. For stage 0 disease, the five-year survival rate is almost 100%. For stage I (early/lymph node negative), the five-year survival rate is also almost 100%. For stage II (early/lymph node positive), five-year survival decreases to 81–92%. For stage III disease (locally advanced), the five-year survival rate is 54–67%. For women with stage IV (metastatic) breast cancer, the five-year survival is about 20%.

Approximately 17% of patients develop lymphedema after axillary lymph node dissection, while only 3% of patients develop lymphedema after sentinel node biopsy. Five percent of women are unhappy with the cosmetic effects of the surgery.

Risks

The risks are similar to those associated with any surgical procedure. Risks include bleeding, infection, breast asymmetry, **anesthesia** reaction, or unexpected scarring. A lumpectomy may also cause loss of sensation in the breast. The size and shape of the breast will be affected by the operation. Fluid can accumulate in the area where tissue was removed, requiring drainage.

If lymph node dissection is performed, there are several potential complications. A woman may experience decreased feeling in the back of her armpit. She may also experience other sensations, including numbness, tingling, or increased skin sensitivity. An inflammation of the arm vein, called phlebitis, can occur. There may be injury to the nerves controlling arm motion.

There is a risk of developing **lymphedema** (swelling of the arm) after axillary lymph node dissection. This swelling can range from mild to very severe. It can be treated with elastic bandages and specialized **physical therapy**, but it is a chronic condition, requiring continuing care. Lymphedema can arise at any time, even years after surgery.

Alternatives

A procedure in which the entire affected breast is removed, called a mastectomy, has been shown to be as equally effective in treating breast cancer as lumpectomy in terms of rates of recurrence and survival. Some women may choose to have a mastectomy because they strongly fear a recurrence of breast cancer, and may consider a lumpectomy too risky. Others may feel uncomfortable with a breast that has had cancer and would experience more peace of mind with the entire breast removed.

Lung abscess

Definition

Lung **abscess** is an acute or chronic infection of the lung, marked by a localized collection of pus within cavities, inflammation, and destruction of the pulmonary tissue (**necrosis** of the lung). Sometimes small abscesses form, which are called lung **gangrene** or necrotizing **pneumonia**. Acute abscesses last for only four to six weeks, while chronic abscesses last much longer.

Demographics

The infection of the lung called lung abscess can affect anyone in the world at any age. Males are more prone to it than females. The frequency of its occurrence in the United States is unknown.

Description

Lung abscess is the end result of a number of different disease processes ranging from fungal and bacterial infections to cancer. The following aerobic bacterial species can lead to lung abscess:

- *Pseudomonas aeruginosa*
- *Klebsiella pneumoniae*
- *Haemophilus influenzae*
- *Staphylococcus aureus*
- *Streptococcus pneumoniae*
- *Streptococcus pyogenes*
- Species within the genus *Nocardia*
- Species within the genus *Actinomyces*
- Fungal species.

The following non-bacterial and atypical bacterial pathogen species can also lead to lung abscess:

WWW.BOOKBAZ.IR

- Parasitic species within the genera *Paragonimus* (flatworms) and *Entamoeba* (amoeba).
- Species within the genus *Mycobacterium*.
- Fungi species within the genera *Aspergillus, Histoplasma, Blastomyces,* and *Coccidioides*.

Patients who are most vulnerable include those weakened by cancer and other chronic diseases; patients with a history of substance abuse including alcohol, diabetes, **epilepsy** and seizures, and poor dental hygiene; patients who have recently had operations under **anesthesia**; and **stroke** patients. The elderly are more likely to have lung abscess than any other age group because of increased risk from **periodontal disease** (disorders in and around the teeth), dysphagia (difficulties with swallowing), and aspiration (entry of foreign material into trachea and lungs). In children, the most vulnerable patients are those with weakened immune systems, **malnutrition**, or blunt injuries to the chest.

Causes and symptoms

The immediate cause of most lung abscesses is infection caused by bacteria. About 65% of these infections are produced by anaerobes, which are bacteria that do not need air or oxygen to live. The remaining cases are caused by a mixture of anaerobic and aerobic (air breathing) bacteria and other pathogens. When the bacteria arrive in the lung, special cells called phagocytes engulf or eat them. The phagocytes release chemicals that contribute to inflammation and eventual necrosis, or death, of a part of the lung tissue. Several different ways are available for bacteria to get into the lungs. Some of them are: aspiration, bronchial obstruction, and spread of infection.

Aspiration

Aspiration refers to the accidental inhalation of material from the mouth or throat into the airway and lungs. It is responsible for about 50% of cases of lung abscess. The human mouth and gums contain large numbers of anaerobic bacteria; patients with periodontal disease or poor **oral hygiene** have higher concentrations of these organisms. Aspiration is most likely to occur in patients who are unconscious or semi-conscious due to anesthesia, seizures, alcohol and drug abuse, or stroke. Patients who have problems swallowing or coughing, or who have nasogastric tubes in place are also at risk of aspiration.

Bronchial obstruction

The bronchi are the two branches of the windpipe that lead into the lungs. If they are blocked by tissue swelling, cancerous tumors, or **foreign objects**, a lung abscess may form from infection trapped behind the blockage.

Spread of infection

About 20% of cases of pneumonia that cause the death of lung tissue (necrotizing pneumonia) will develop into lung abscess. Lung abscess can also be caused by the spread of other infections from the liver, abdominal cavity, or open chest **wounds**. Rarely, acquired immune deficiency syndrome (**AIDS**) patients can develop lung abscess from *Pneumocystis carinii* and other organisms that take advantage of a weakened immune system.

Lung abscess is usually slow to develop. It may take about two weeks after aspiration or bronchial obstruction for an abscess to produce noticeable symptoms. The patient may be acutely ill for two weeks to three months. In the beginning, the symptoms of lung abscess are difficult to distinguish from those of severe pneumonia. Adults will usually have moderate **fever** (101–102°F/38–39°C), chills, chest **pain**, and general weakness. Children may or may not have chest pain, but usually suffer weight loss and high fevers. As the illness progresses, about 75% of patients will **cough** up foul or musty-smelling sputum; some also cough up blood.

Lung abscess can lead to serious complications, including **emphysema**, spread of the abscess to other parts of the lung, hemorrhage, **adult respiratory distress syndrome**, rupture of the abscess, inflammation of the membrane surrounding the heart, or chronic inflammation of the lung.

Symptoms of lung abscess is dependent on whether the abscess is caused by anaerobic bacterial infection or other pathogens. If it is caused by anaerobic bacterial infection, patients often have symptoms that slowly appear over a matter of weeks to months. Common symptoms are cough with mucus, fever, night sweats, weight loss, and anorexia. If lung abscess is caused by other pathogens, the symptoms come on more quickly. However, abscesses from fungi and species within the bacterial genera *Nocardia* and *Mycobacteria* often produce more gradual symptoms that progressively worsen.

Diagnosis

The diagnosis is made on the basis of the patient's medical history (especially recent operations under general anesthesia) and general health as well as imaging studies. Smears and cultures taken from the

KEY TERMS

Abscess—An area of injured body tissue that fills with pus, as in lung abscess.

Anaerobe—A type of bacterium that does not require air or oxygen to live. Anaerobic bacteria are frequent causes of lung abscess.

Aspiration—Inhalation of fluid or foreign bodies into the airway or lungs. Aspiration often happens after vomiting.

Bronchoscope—A lighted, flexible tube inserted into the windpipe to view the bronchi or withdraw fluid samples for testing. Bronchoscopy with a protected brush can be used in the diagnosis of lung abscess in severely ill patients.

Bronchus—One of the two large tubes connecting the windpipe and the lungs.

Leukocytosis—An increased level of white cells in the blood. Leukocytosis is a common reaction to infections, including lung abscess.

Necrotizing pneumonia—Pneumonia that causes the death of lung tissue. It often precedes the development of lung abscess.

Sputum—The substance that is brought up from the lungs and airway when a person coughs or spits. It is usually a mixture of saliva and mucus, but may contain blood or pus in patients with lung abscess or other diseases of the lungs.

patient's sputum for microbiologic diagnosis are not usually very helpful because they will be contaminated with bacteria from the mouth. The doctor will first use a bronchoscope (lighted tube inserted into the windpipe) to rule out the possibility of lung cancer. In some cases of serious infection, the doctor can use a fiberoptic bronchoscope with a protected specimen brush to take material directly from the patient's lungs, for identification of the organism. This technique is time-consuming and expensive, and requires the patient to be taken off **antibiotics** for 48 hours. It is usually used only to evaluate severely ill patients with weakened immune systems.

In most cases, the doctor will use the results of a chest x ray to help distinguish lung abscess from **empyema**, cancer, **tuberculosis**, or cysts. In patients with lung abscess, the x ray scan will show a thick-walled unified clear space or cavity surrounded by solid tissue. There is often a visible air-fluid level. The doctor may also order a computed tomography (CT) scan of the chest, in order to have a clearer picture of the exact location of the abscess.

Blood tests cannot be used to make a diagnosis of lung abscess, but they can be useful in ruling out other conditions. Patients with lung abscess usually have abnormally high white blood cell counts (**leukocytosis**) when their blood is tested, but this condition is not unique to lung abscess.

Treatment

Lung abscess is treated with a combination of antibiotic drugs, **oxygen therapy**, and surgery. The antibiotics that are usually given for lung abscess are penicillin G, penicillin V, and clindamycin. They are given intravenously until the patient shows signs of improvement, and then they are continued in oral form. The patient may need to take antibiotics for a month or longer, until the chest x ray indicates that the abscess is healing. Oxygen may be given to patients who are having trouble breathing.

Surgical treatment

Most patients with lung abscess will not need surgery. About 5% of patients—usually those who do not respond to antibiotics or are coughing up large amounts of blood (500 milliliters or more)—may have emergency surgery for removal of the diseased part of the lung or for insertion of a tube to drain the abscess. Antibiotic treatment is considered to have failed if fever and other symptoms continue after ten to 14 days of treatment; if chest x rays indicate that the abscess is not shrinking; or if the patient has pneumonia that is spreading to other parts of the lung.

Supportive care

Because lung abscess is a serious condition, patients need quiet and bed rest. Hospital care usually includes increasing the patient's fluid intake to loosen up the secretions in the lungs, and **physical therapy** to strengthen the patient's breathing muscles.

Follow-up

Patients with lung abscess need careful follow-up care after the acute infection subsides. Follow-up

WWW.BOOKBAZ.IR

usually includes a series of chest x rays to make sure that the infection has cleared up. Treatment with antibiotics may continue for as long as four months, to prevent recurrence.

Prognosis

About 90–95% of lung abscess patients can be treated successfully with antibiotics alone. Patients who need surgical treatment have a mortality rate of 10–15%. Those that have higher risks of death from lung abscess are anyone with malnutrition, human **immunodeficiency** virus (HIV), or mental debilitation, and the elderly. Those with HIV and other immunocompromised conditions also have a high mortality rate.

Prevention

Some of the conditions that make people more vulnerable to lung abscess concern long-term lifestyle behaviors, such as substance abuse and lack of dental care. Others, however, are connected with chronic illness and hospitalization. Aspiration can be prevented with proper care of unconscious patients, which includes suctioning of throat secretions and positioning patients to promote drainage. Conscious patients can be given physical therapy to help them cough up material in their lungs and airways. Patients with weakened immune systems can be isolated from patients with pneumonia or **fungal infections**.

Lung biopsy

Definition

Lung biopsy is a procedure for obtaining a small sample of lung tissue for examination. The tissue is usually examined under a microscope and may be sent to a microbiological laboratory for culture. Microscopic examination is performed by a pathologist.

Purpose

A lung biopsy is usually performed to determine the cause of abnormalities, such as nodules that appear on chest x-rays. It can confirm a diagnosis of cancer, especially if malignant cells are detected in the patient's sputum or bronchial washing. In addition to evaluating lung tumors and their associated symptoms, lung biopsies may be used to diagnose lung infections, especially **tuberculosis** and **Pneumocystis pneumonia**, drug reactions, and chronic diseases of the lungs such as **sarcoidosis** and **pulmonary fibrosis**.

A lung biopsy can be used for treatment as well as diagnosis. **Bronchoscopy**, a type of lung biopsy performed with a long, flexible slender instrument called a bronchoscope, can be used to clear a patient's air passages of secretions and to remove airway blockages.

Demographics

Lung cancer accounts for more than a quarter of cancer-related deaths in the United States. According to the American Cancer Society, about 228,190 patients were newly diagnosed with lung cancer in 2013 (118,080 in men and 110,110 in women), with 159,480 deaths. Lung cancer kills more people than cancers of the breast, prostate, and colon combined. Cigarette **smoking** accounts for nearly 90% of cases of lung cancer in the United States.

Description

The right and left lungs are separated by the mediastinum, which contains the heart, trachea, lymph nodes, and esophagus. Lung biopsies sometimes involve **mediastinoscopy**.

Types of lung biopsies

Lung biopsies are performed using a variety of techniques, depending on where the abnormal tissue is located in the lung, the health and age of the patient, and the presence of lung disease. A bronchoscopy is ordered if a lesion identified on the x-ray seems to be located on the wall (periphery) of the chest. If the

KEY TERMS

Bronchoscopy—A medical test that enables the physician to see the breathing passages and the lungs through a hollow, lighted tube.

Chest x-ray—Brief exposure of the chest to radiation to produce an image of the chest and its internal structures.

Endotracheal tube—A hollow tube that is inserted into the windpipe to administer anesthesia.

Lymph nodes—Small, bean-shaped structures that serve as filters, scattered along the lymphatic vessels. Lymph nodes trap bacteria or cancer cells that are traveling through the lymphatic system.

Malignant—Cancerous.

Mediastinoscopy—A procedure that allows the physician to see the organs in the mediastinal space using a thin, lighted, hollow tube (a mediastinoscope).

Mediastinum—The area between the lungs, bounded by the spine, breastbone, and diaphragm.

Pleural cavity—The space between the lungs and the chest wall.

Pneumothorax—A condition in which air or gas enters the pleura (area around the lungs) and causes a collapse of the lung.

Pulmonary nodule—Also called a lung nodule; a lesion surrounded by normal lung tissue. Nodules may be caused by bacteria, fungi, or a tumor (benign or cancerous).

Sputum—A mucus-rich secretion that is coughed up from the passageways (bronchial tubes) and the lungs.

Sputum cytology—A lab test in which a microscope is used to check for cancer cells in the sputum.

Thoracentesis—Removal of fluid from the pleural cavity.

suspicious area lies close to the chest wall, a needle biopsy can be done. If both methods fail to diagnose the problem, an open lung biopsy may be performed. When there is a question about whether the lung cancer or suspicious mass has spread to the lymph nodes in the mediastinum, a mediastinoscopy is performed.

BRONCHOSCOPIC BIOPSY. During the bronchoscopy, a thin, lighted tube (bronchoscope) is passed from the nose or mouth down the windpipe (trachea) to the air passages (bronchi) leading to the lungs. Through the bronchoscope, the physician views the airways and is able to clear mucus from blocked airways and collect cells or tissue samples for laboratory analysis.

NEEDLE BIOPSY. During a needle biopsy procedure, the patient is mildly sedated but awake. He or she sits in a chair with arms folded in front on a table. An x-ray technician uses a computerized axial tomography (CAT) scanner or a fluoroscope to identify the precise location of the suspicious areas. Markers are placed on the overlying skin to identify the biopsy site. The skin is thoroughly cleansed with an antiseptic solution, and a local anesthetic is injected to numb the area. The patient will feel a brief stinging sensation when the anesthetic is injected.

The physician makes a small incision, about half an inch (1.25 cm) in length. The patient is asked to take a deep breath and hold it while the physician inserts the biopsy needle through the incision into the lung tissue to be biopsied. The patient may feel pressure and a brief sharp **pain** when the needle touches the lung tissue. Most patients do not experience severe pain. The patient should refrain from coughing during the procedure. The needle is withdrawn when enough tissue has been obtained. Pressure is applied at the biopsy site and a sterile bandage is placed over the incision. A **chest x-ray** is performed immediately after the procedure to check for potential complications. The entire procedure takes 30–60 minutes.

OPEN BIOPSY. Open biopsies are performed in a hospital operating room under general **anesthesia**. Once the anesthesia has taken effect, the surgeon makes an incision over the lung area, a procedure called a thoracotomy. Some lung tissue is removed and the incision is closed with sutures. Chest tubes are placed with one end inside the lung and the other end protruding through the closed incision. Chest tubes are used to drain fluid and blood and re-expand the lungs. They are usually removed the day after the procedure. The entire procedure normally takes about an hour. A chest x-ray is performed immediately after the procedure to check for potential complications.

VIDEO-ASSISTED THORACOSCOPIC SURGERY. A minimally invasive technique, video-assisted thoracoscopic surgery (VATS) can be used to biopsy lung and mediastinal lesions. VATS may be performed on select patients in place of open lung biopsy. While the patient is under general anesthesia, the surgeon makes several small incisions in the chest wall. A thoracoscope—a thin, hollow, lighted tube with a tiny video camera mounted on it—is inserted through

WWW.BOOKBAZ.IR

one of the small incisions. The other incisions allow the surgeon to insert special instruments to retrieve tissue for biopsy.

MEDIASTINOSCOPY. This procedure is performed under general anesthesia. A 2–3 in. (5–8 cm) incision is made at the base of the neck. A thin, hollow, lighted tube called a mediastinoscope is inserted through the incision into the space between the right and the left lungs. The surgeon removes any lymph nodes or tissues that look abnormal. The mediastinoscope is then removed, and the incision is sutured and bandaged. A mediastinoscopy takes about an hour.

Diagnosis

Before scheduling a lung biopsy, the physician performs a careful evaluation of the patient's medical history and symptoms and performs a **physical examination**. Chest x-rays and sputum **cytology** (examination of cells obtained from a deep-cough mucus sample) are other diagnostic tests that may be performed. An electrocardiogram (EKG) and laboratory tests may be performed before the procedure to check for blood clotting problems, anemia, and blood type, should a **transfusion** become necessary.

Preparation

Fiberoptic bronchoscopy is performed by pulmonologists, physician specialists in pulmonary medicine. CAT-guided needle biopsy is done by interventional radiologists, physician specialists in radiological procedures. Thoracic surgeons perform open biopsies and VATS. Specially trained nurses and x-ray and laboratory technicians assist during the procedures and provide pre- and postoperative education and supportive care.

The procedures are performed in an operating or procedure room in a hospital.

During a preoperative appointment, usually scheduled within one to two weeks before the procedure, the patient receives information about what to expect during the procedure and the recovery period. During this appointment or just before the procedure, the patient usually meets with the physician (or physicians) performing the procedure (the pulmonologist, interventional radiologist, or thoracic surgeon).

A chest x ray or CAT scan of the chest is used to identify the area to be biopsied.

About an hour before the biopsy procedure, the patient receives a sedative. Medication may also be given to dry up airway secretions. General anesthesia is not used for this procedure.

For at least 12 hours before the open biopsy, VATS, or mediastinoscopy procedures, the patient should not eat or drink anything. Prior to these procedures, an intravenous line is placed in the patient's arm to deliver medications or fluids as necessary. A hollow tube, called an endotracheal tube, is passed through the patient's mouth into the airway leading to the lungs. Its purpose is to deliver the general anesthetic. The chest area is cleansed with an antiseptic solution. In the mediastinoscopy procedure, the neck is also cleansed to prepare for the incision.

Smoking cessation

Patients who will undergo surgical diagnostic and treatment procedures should be encouraged to stop smoking and stop using tobacco products. The patient needs to make the commitment to be a nonsmoker after the procedure. Patients able to stop smoking several weeks before surgical procedures have fewer postoperative complications. The patient should ask a health care provider for more information if he or she needs help with smoking cessation.

Informed consent

Informed consent is an educational process between health care providers and patients. Before any procedure is performed, the patient is asked to sign a consent form. Prior to signing the form, the patient should understand the nature and purpose of the diagnostic procedure or treatment, its risks and benefits, and alternatives, including the option of not proceeding with the test or treatment. During the discussions, the health care providers should answer the patient's questions about the consent form or procedure.

Aftercare

Needle biopsy

Following a needle biopsy, the patient is allowed to rest comfortably. He or she may be required to lie flat for two hours following the procedure to prevent the risk of bleeding. The nurse checks the patient's status at two-hour intervals. If there are no complications after four hours, the patient can go home once he or she has received instructions about resuming normal activities. The patient should rest at home for a day or two before returning to regular activities and should avoid strenuous activities for one week after the biopsy.

Open biopsy, VATS, or mediastinoscopy

After an open biopsy, VATS, or mediastinoscopy, the patient is taken to the recovery room for

observation. The patient receives oxygen via a face mask or nasal cannula. If no complications develop, the patient is taken to a hospital room. Temperature, blood oxygen level, pulse, blood pressure, and respiration are monitored. Chest tubes remain in place after surgery to prevent the lungs from collapsing and to remove blood and fluids. The tubes are usually removed the day after the procedure.

The patient may experience some grogginess for a few hours after the procedure. He or she may have a **sore throat** from the endotracheal tube. The patient may also have some pain or discomfort at the incision site, which can be relieved by pain medication. It is common for patients to require some pain medication for up to two weeks following the procedure.

After receiving instructions about resuming normal activities and caring for the incision, the patient usually goes home the day after surgery. The patient should not drive while taking narcotic pain medication.

Patients may experience **fatigue** and muscle aches for a day or two because of the general anesthesia. The patient can gradually increase activities as tolerated. Walking is recommended. Sutures are usually removed after one to two weeks.

The physician should be notified immediately if the patient experiences extreme pain, light-headedness, or difficulty breathing after the procedure. Sputum may be slightly bloody for a day or two after the procedure. Heavy or persistent bleeding requires evaluation by the physician.

Results

Normal results indicate no evidence of infection in the lungs, no detection of lumps or nodules, and cells that are free from cancerous abnormalities.

Abnormal results of needle biopsy, VATS, and open biopsy may be associated with diseases other than cancer. Nodules in the lungs may be due to active infections such as tuberculosis, or may be **scars** from a previous infection. In 33% of biopsies using a mediastinoscope, the biopsied lymph nodes prove to be cancerous. Abnormal results should always be considered in the context of the patient's medical history, physical examination, and other tests such as sputum examination and chest x-rays before a final diagnosis is made.

Morbidity and mortality rates

The risk of death from needle biopsy is rare. The risk of death from open biopsy is one in 3,000 cases. In mediastinoscopy, death occurs in fewer than one in 3,000 cases.

Risks

Lung biopsies should not be performed on patients who have a bleeding disorder or abnormal blood clotting because of low platelet counts, or who have a prolonged **prothrombin time** (PT) or **partial thromboplastin time** (PTT). Platelets are small blood cells that play a role in the blood clotting process. PT and PTT measure how well blood is clotting. If clotting times are prolonged, it may be unsafe to perform a biopsy because of the risk of bleeding. If the **platelet count** is lower than 50,000/cubic mm, the patient may be given a platelet transfusion as a temporary relief measure, and a biopsy can then be performed.

In addition, lung biopsies should not be performed if other tests indicate the patient has enlarged alveoli associated with **emphysema**, **pulmonary hypertension**, or enlargement of the right ventricle of the heart (**cor pulmonale**).

The normal risks of any surgical procedure include bleeding, infection, or **pneumonia**. The risk of these complications is higher in patients undergoing open biopsy procedures, as is the risk of pneumothorax (lung collapse). In rare cases, the lung collapses because of air that leaks in through the hole made by the biopsy needle. A chest x-ray is done immediately after the biopsy to detect the development of this potential complication. If a pneumothorax occurs, a chest tube is inserted into the pleural cavity to re-expand the lung. Signs of pneumothorax include **shortness of breath**, rapid heart rate, or blueness of the skin (a late sign). If the patient has any of these symptoms after being discharged from the hospital, it is important to call the health care provider or emergency services immediately.

Bronchoscopic biopsy

Bronchoscopy is generally safe, and complications are rare. If they do occur, complications may include spasms of the bronchial tubes that can impair breathing, irregular heart rhythms, or infections such as pneumonia.

Needle biopsy

Needle biopsy is associated with fewer risks than open biopsy because it does not involve general anesthesia. Some **hemoptysis** (coughing up blood) occurs in 5% of needle biopsies. Prolonged bleeding or

WWW.BOOKBAZ.IR

infection may also occur, although these are very rare complications.

Open biopsy

Possible complications of an open biopsy include infection or pneumothorax. If the patient has very severe breathing problems before the biopsy, breathing may be further impaired following the operation. Patients with normal lung function prior to the biopsy have a very small risk of respiratory problems resulting from or following the procedure.

Mediastinoscopy

Complications due to mediastinoscopy are rare. Possible complications include pneumothorax or bleeding caused by damage to the blood vessels near the heart. Mediastinitis, or infection of the mediastinum, may develop. Injury to the esophagus or larynx may occur. If the nerves leading to the larynx are injured, the patient may be left with a permanently hoarse voice. All of these complications are rare.

Alternatives

The type of alternative diagnostic procedures available depend upon each patient's diagnosis.

Some people may be eligible to participate in clinical trials, research programs conducted with patients to evaluate a new medical treatment, drug, or device. The purpose of clinical trials is to find new and improved methods of treating different diseases and special conditions.

The National Cancer Institute (NCI) has conducted a clinical trial to evaluate low-dose helical computed tomography for its effectiveness in screening for lung cancer. One study concluded that this test is more sensitive in detecting specific conditions related to lung cancer than other screening tests.

Lung cancer, non-small cell

Definition

Non-small cell lung cancer (NSCLC) is a disease in which the cells of the lung tissues grow uncontrollably and form tumors.

Demographics

Worldwide, lung cancer is the most common cancer in males, and the fifth most common cancer in women. The worldwide mortality rate for patients with lung cancer is 86%. In the United States, lung cancer is the leading cause of death from cancer among both men and women. The World Health Organization estimates that the worldwide mortality from lung cancer will increase to three million by the year 2025. Of those three million deaths, almost two and a half million will result from non-small cell lung cancer.

The American Cancer Society (ACS) estimates that 224,210 Americans developed lung cancer in 2014, 116,000 men and 108,210 women. Of these patients, 159,260 will die of the disease.

The incidence of lung cancer is beginning to fall in developed countries. This may be a result of antismoking campaigns. In developing countries, however, rates continue to rise, which may be a consequence of both industrialization and the increasing use of tobacco products.

Description

There are two kinds of lung cancers, primary and secondary. Primary lung cancer starts in the lung itself, and is divided into **small cell lung cancer** and non-small cell lung cancer. Small cell lung cancers are shaped like an oat and called oat-cell cancers; they are aggressive, spread rapidly, and represent 20% of lung cancers. Non-small cell lung cancer represents almost 80% of all primary lung cancers. Secondary lung cancer is cancer that starts somewhere else in the body (for example, the breast or colon) and spreads to the lungs.

The lungs

The lungs are located along with the heart in the chest cavity. The lungs are not simply hollow balloons but have a very organized structure consisting of hollow tubes, blood vessels and elastic tissue. The hollow tubes, called bronchi, are highly branched, becoming smaller and more numerous at each branching. They end in tiny, blind sacs made of elastic tissue called alveoli. These sacs are where the oxygen a person breathes in is taken up into the blood, and where carbon dioxide moves out of the blood to be breathed out.

Normal healthy lungs are continually secreting mucus that not only keeps the lungs moist, but also protects the lungs by trapping foreign particles like dust and dirt in breathed air. The inside of the lungs is covered with small hairlike structures called cilia. The cilia move in such a way that mucus is swept up out of the lungs and into the throat.

Lung cancer

Most lung cancers start in the cells that line the bronchi, and can take years to develop. As they grow larger they prevent the lungs from functioning normally. The tumor can reduce the capacity of the lungs, or block the movement of air through the bronchi in the lungs. As a result, less oxygen gets into the blood and patients feel short of breath. Tumors may also block the normal movement of mucus up into the throat. As a result, mucus builds up in the lungs and infection may develop behind the tumor. Once lung cancer has developed it frequently spreads to other parts of the body.

The speed at which non-small cell tumors grow depends on the type of cells that make up the tumor. The following three types account for the vast majority of non-small cell tumors:

- Adenocarcinomas are the most common and often cause no symptoms. Frequently they are not found until they are advanced.
- Squamous cell carcinomas usually produce symptoms because they are centrally located and block the lungs.

WWW.BOOKBAZ.IR

- Undifferentiated large cell and giant cell carcinomas tend to grow rapidly, and spread quickly to other parts of the body.

Causes and symptoms

Causes

Tobacco **smoking** accounts for 87% of all lung cancers. Giving up tobacco can prevent most lung cancers. Smoking **marijuana** cigarettes is considered another risk factor for cancer of the lung. Second hand smoke also contributes to the development of lung cancer among nonsmokers.

Certain hazardous materials that people may be exposed to in their jobs have been shown to cause lung cancer. These include asbestos, coal products, and radioactive substances. Air pollution may also be a contributing factor. Exposure to radon, a colorless, odorless gas that sometimes accumulates in the basement of homes, may cause lung cancer in a tiny minority of patients. In addition, patients whose lungs are scarred from other lung conditions may have an increased risk of developing lung cancer.

Symptoms

Lung cancers tend to spread very early, and only 15% are detected in their early stages. The chances of early detection, however, can be improved by seeking medical care at once if any of the following symptoms appear:

- a cough that does not go away
- chest pain
- shortness of breath
- recurrent lung infections, such as bronchitis or pneumonia
- bloody or brown-colored spit or phlegm (sputum)
- persistent hoarseness
- significant weight loss that is not due to dieting or vigorous exercise; fatigue and loss of appetite
- unexplained fever

Although these symptoms may be caused by diseases other than lung cancer, it is important to consult a doctor to rule out the possibility of lung cancer.

If lung cancer has spread to other organs, the patient may have other symptoms such as headaches, bone **fractures**, **pain**, bleeding, or **blood clots**.

Diagnosis

Physical examination and diagnostic tests

The doctor will first take a detailed medical history and assess risk factors. During a complete **physical examination** the doctor will examine the patient's throat to rule out other possible causes of hoarseness or coughing, and will listen to the patient's breathing and chest sounds.

If the doctor has reason to suspect lung cancer, particularly if the patient has a history of heavy smoking or occupational exposure to irritating substances, a chest x ray may be ordered to see if there are any masses in the lungs. Special imaging techniques, such as computed tomography (CT) scans or **magnetic resonance imaging** (MRI), may provide more precise information about the size, shape, and location of any tumors.

Sputum analysis

Sputum analysis is a noninvasive test that involves microscopic examination of cells that are coughed up from the lungs. This test can diagnose at least 30% of lung cancers, even if tumors are not visible on chest x rays. In addition, the test can detect cancer in its very early stages, before it spreads to other regions. The sputum test does not provide any information about the location of the tumor.

Lung biopsy

Lung biopsy is the most definitive diagnostic tool for cancer. It can be performed in three different ways. **Bronchoscopy** involves the insertion of a slender, lighted tube, called a bronchoscope, down the patient's throat and into the lungs. This test allows the doctor to see the tubes inside the lungs, and to obtain samples of lung tissue. If a needle biopsy is to be performed, the location of the tumor is first identified using a computerized tomography (CT) scan or magnetic resonance imaging (MRI). The doctor then inserts a needle through the chest wall and collects a sample of tissue from the tumor. In the third procedure, known as surgical biopsy, the chest wall is opened up and a part of the tumor, or all of it, is removed. A doctor who specializes in the study of diseased tissue (a pathologist) examines the tumor to identify the cancer's type and stage.

Treatment

Staging

Treatment for non-small cell lung cancer depends primarily on the stage of the cancer. Staging is a

process that tells the doctor if the cancer has spread and the extent of its spread. The most commonly used treatments are surgery, **radiation therapy**, and **chemotherapy**.

Non-small cell lung cancer has six stages:

- Occult carcinoma. Cancer cells have been found in the sputum, but no tumor has yet been found.
- Stage 0. A small group of cancerous cells have been found in one location.
- Stage I. The cancer is only in the lung and has not spread anywhere else.
- Stage II. The cancer has spread to nearby lymph nodes.
- Stage III. The cancer has spread to more distant lymph nodes, and/or other parts of the chest like the diaphragm.
- Stage IV. The cancer has spread to other parts of the body.

Surgery

Surgery is the standard treatment for the earlier stages of non-small cell lung cancer. The surgeon will decide on the type of surgery, depending on how much of the lung is affected. There are three different types of surgical procedures:

- Wedge resection is the removal of a small part of the lung.
- Lobectomy is the removal of one lobe of the lung. (The right lung has three lobes and the left lung has two lobes.)
- Pneumonectomy is the removal of an entire lung.

Lung surgery is a major procedure and patients can expect to experience pain, weakness in the chest, and **shortness of breath**. Air and fluid collect in the chest after surgery. As a result, patients will need help to turn over, **cough**, and breath deeply. Patients should be encouraged to perform these activities because they help get rid of the air and fluid and speed up recovery. It can take patients several months before they regain their energy and strength.

Radiotherapy

Patients whose cancer has progressed too far for surgery (Stages III and IV) may receive radiotherapy. Radiotherapy involves the use of high-energy rays to kill cancer cells. It is used either by itself or in combination with surgery or chemotherapy. The amount of radiation used depends on the size and the location of the tumor.

Radiation therapy may produce such side effects as tiredness, skin **rashes**, upset stomach, and **diarrhea**. Dry or sore throats, difficulty in swallowing, and loss of hair in the treated area are all minor side effects of radiation. These may disappear either during the course of the treatment or after the treatment is over.

Chemotherapy

Chemotherapy is also given to patients whose cancer has progressed too far for surgery. Chemotherapy is medication that is usually given intravenously to kill cancer cells. These drugs enter the bloodstream and travel to all parts of the body, killing cancer cells that have spread to different organs. Chemotherapy is used as the primary treatment for cancers that have spread beyond the lung and cannot be removed by surgery. It can also be used in addition to surgery or radiation therapy.

Chemotherapy for NSCLC has made significant advances since the early 1980s in improving the patient's quality of life as well as length of survival. Newer cytotoxic (cell-killing) agents developed in the 1990s, such as the taxanes, are typically combined with either cisplatin or carboplatin as first-line therapy for non-small cell lung cancer.

Drugs for lung cancer developed since 2000 include gefinitib (Iressa) and pemetrexed (Alimta). The FDA approved gefinitib in May 2003 as a treatment for patients with NSCLC who have not responded to platinum-based or taxane chemotherapy. It is taken by mouth and works by inhibiting an enzyme involved in the growth of tumor cells. Pemetrexed, which is given by injection, was approved by the FDA in February 2004 for the treatment of **mesothelioma**, a type of lung cancer caused by exposure to asbestos fibers. However, the drug appears to be effective in treating other types of lung cancer as well.

Chemotherapy is also used as palliative treatment for non-small cell lung cancer. Palliative refers to any type of therapy that is given to relieve the symptoms of a disease but not to cure it.

Clinical trials

Patients diagnosed with non-small cell lung cancer should discuss participating in clinical trials with their doctor. There are many clinical trials currently underway that are investigating all different stages of the disease. These trials are studying various new treatment options including:

- Chemotherapy with new drugs, and combinations of drugs

WWW.BOOKBAZ.IR

- Courses of chemotherapy prior to surgery
- Radiotherapy after surgery
- Chemotherapy and radiotherapy in combination

Information on open clinical trials is available on the Internet from the National Cancer Institute at http://cancertrials.nci.nih.gov.

Alternatives

Because non-small cell lung cancer has a poor prognosis with conventional medical treatment, many patients are willing to try complementary and alternative therapies. These therapies are used to try to reduce **stress**, ease side effects and symptoms, or control disease. Two treatments sometimes used are shark cartilage and mistletoe. Although shark cartilage is thought to interfere with the tumor's blood supply, clinical trials have so far been inconclusive. Mistletoe is a poisonous plant that has been shown to kill cancer cells in the laboratory. Again, however, clinical trials with cancer patients have been inconclusive.

Patients who decide to try complementary and alternative therapies should tell their doctors. Some of these therapies may interfere with conventional treatment.

Coping with cancer treatment

The side effects associated with treatment of non-small cell lung cancer can be severe. Patients should ask their doctors about medications to treat **nausea and vomiting**, and other side effects. It is particularly important to eat a nutritious diet and to drink plenty of fluids. In addition, most patients report feeling very tired and should get plenty of rest.

Patients should consider joining local support groups with people who are coping with the same experiences. Many people with cancer find they can share thoughts and feelings with group members that they do not feel comfortable sharing with friends or family. Support groups are also a good source of information about coping with cancer.

Prognosis

The prognosis for non-small cell lung cancer is better if the disease is found early, and removed surgically. For patients whose disease is caught in Stage I, the survival rate five years after surgery ranges from 60% to 80%. Up to 55% of Stage II patients are alive after five years, but only about 30% of Stage III patients make it to five years. Unfortunately, 85% of patients already have at least Stage III cancer by the time they are diagnosed. Many of these patients have disease that is too advanced for surgery. Despite treatment with radiotherapy and chemotherapy, the five-year survival for patients with inoperable disease is extremely low.

KEY TERMS

Bronchi—The tubes that carry air into the lungs.

Lymph—Clear fluid containing white blood cells that is collected from the tissues of the body and flows in vessels called the lymphatic system.

Lymph node—Small oval-shaped filters in the lymphatic system that trap bacteria and other unwanted particles to ensure their removal from the body.

Palliative—Referring to any type of treatment that is given to relieve the symptoms of a disease rather than to cure it.

Respiratory distress—A condition in which patients with lung disease are not able to get enough oxygen.

Prevention

The best way to prevent lung cancer is not to start smoking or to quit smoking. Secondhand smoke from other people's tobacco should also be avoided. Appropriate precautions should be taken when working with cancer-causing substances (**carcinogens**). Testing houses for the presence of radon gas, and removing asbestos from buildings have also been suggested as preventive strategies.

Lung cancer, small cell

Definition

Small cell lung cancer is a disease in which the cells of the lung tissues grow uncontrollably and form tumors.

Demographics

Lung cancer is a growing global epidemic. Worldwide, lung cancer is the second most common cancer among both men and women and is the leading cause of cancer death in both sexes. The worldwide mortality rate for patients with lung cancer is 86%. Of the 160,000 deaths from lung cancer that occur annually in the United States, about 40,000 are caused by small cell lung cancer. Although there are differences in mortality rates between ethnic groups, this is mainly due to differences in **smoking** habits.

Description

Lung cancer is divided into two main types: small cell and non-small cell. Small cell lung cancer is the least common of the two, accounting for only about 10–15% of all lung cancers. In the past, the disease was called oat cell cancer because, when viewed under a microscope, the cancer cells resemble oats. This type of lung cancer grows quickly and is more likely to spread to other organs in the body.

The lungs are located along with the heart in the chest cavity. The lungs are not simply hollow balloons, but have a very organized structure consisting of hollow tubes, blood vessels, and elastic tissue. The hollow tubes, called bronchi, are multi-branched, becoming smaller and more numerous at each branching. They end in tiny, blind sacs made of elastic tissue called alveoli. These sacs are where the oxygen a person breathes in is taken up into the blood, and where carbon dioxide moves out of the blood to be breathed out.

Normal, healthy lungs are continually secreting mucus that not only keeps the lungs moist, but also protects the lungs by trapping foreign particles like dust and dirt in breathed air. The inside of the lungs is covered with small, hair-like structures called cilia. The cilia move in such a way that mucus is swept up out of the lungs and into the throat.

Small cell lung tumors usually start to develop in the central bronchi. They grow quickly and prevent the lungs from functioning at their full capacity. Tumors may block the movement of air through the bronchi in the lungs. As a result, less oxygen gets into the blood and patients feel short of breath. Tumors may also block the normal movement of mucus into the throat. As a result, mucus builds up in the lungs and infection may develop behind the tumor.

Causes and symptoms

Causes

Tobacco smoking accounts for nearly 90% of all lung cancers. The risk of developing lung cancer is increased for smokers who start at a young age, and for those who have smoked for a long time. The risk also increases as more cigarettes are smoked, and when cigarettes with higher tar content are smoked.

WWW.BOOKBAZ.IR

Smoking **marijuana** cigarettes is also a risk factor for lung cancer. These cigarettes have a higher tar content than tobacco cigarettes.

Certain hazardous materials that people may be exposed to in their jobs have been shown to cause lung cancer. These include asbestos, coal products, and radioactive substances. Air pollution may also be a contributing factor. Exposure to radon, a colorless, odorless gas that sometimes accumulates in the basement of homes, may cause lung cancer in some patients. In addition, patients whose lungs are scarred from other lung conditions may have an increased risk of developing lung cancer.

Although the exact cause of lung cancer is not known, people with a family history of lung cancer appear to have a slightly higher risk of contracting the disease.

Symptoms

Small cell lung cancer is an aggressive disease that spreads quickly. Symptoms depend on the tumor's location within the lung, and on whether the cancer has spread to other parts of the body. More than 80% of small cell lung cancer patients have symptoms for only three months or less, and few cases are detected early. The following symptoms are the most commonly reported by small cell lung cancer patients at the time of their diagnosis:

- a persistent cough
- chest pain
- shortness of breath and wheezing
- persistent hoarseness
- fatigue and loss of appetite

Although some patients may experience bloody spit or phlegm, this symptom is more commonly seen in patients with other types of lung cancer.

Small cell tumors often press against a large blood vessel near the lungs called the superior vena cava (SVC), causing a condition known as SCV syndrome. This condition may cause patients to retain water, **cough**, and have **shortness of breath**. Because small cell lung cancer often spreads quickly to the bones and central nervous system, patients may also have bone **pain**, headaches, and seizures.

Small cell lung cancer can cause several hormonal disorders. About 40% of patients begin to secrete an anti-diuretic hormone at the wrong time. This hormone causes the body to retain water, which may result in the patient experiencing confusion, seizures, or **coma**. Less common are the development of Cushing's syndrome and the Eaton-Lambert syndrome. Symptoms of Cushing's syndrome include **obesity**, severe **fatigue**, high blood pressure, backache, high blood sugar, easy bruising, and bluish-red stretch marks on the skin. Eaton-Lambert syndrome is a neuromuscular disorder that causes muscle weakness, fatigue, and a tingling sensation on the skin. All of these hormonal disorders usually diminish after the lung tumor is successfully treated.

Diagnosis

If lung cancer is suspected, the doctor will take a detailed medical history that checks both symptoms and risk factors. During a complete **physical examination**, the doctor will examine the patient's throat to rule out other possible causes of hoarseness or coughing, and listen to the patient's breathing and the sounds made when the patient's chest and upper back are tapped. A chest x ray may be ordered to check for masses in the lungs. Special imaging techniques, such as computed tomography (CT) scans or **magnetic resonance imaging** (MRI), may provide more precise information about the size, shape, and location of any tumors.

Sputum analysis involves microscopic examination of the cells that are either coughed up from the lungs, or are collected through a special instrument called a bronchoscope. The sputum test does not, however, provide any information about the location of the tumor and must be followed by other tests.

Lung biopsy is the most definitive diagnostic tool for cancer. It can be performed in several different ways. The doctor can perform a **bronchoscopy**, which involves the insertion of a slender, lighted tube, called a bronchoscope, down the patient's throat and into the lungs. In addition to viewing the passageways of the lungs, the doctor can use the bronchoscope to obtain samples of the lung tissue. In another procedure known as a needle biopsy, the location of the tumor is first identified using a CT scan or MRI. The doctor then inserts a needle through the chest wall and collects a sample of tissue from the tumor. In the third procedure, known as surgical biopsy, the chest wall is opened up and a part of the tumor, or all of it, is removed for examination.

Treatment

Staging

Staging procedures are important in lung cancer because they tell doctors whether patients have disease only in their lungs, or whether the cancer has spread to other parts of the body. To establish the cancer stage, doctors have to perform various tests. These may include **bone marrow aspiration and biopsy**, CT scans of the chest and abdomen, MRI scans of the brain, and radionuclide bone scans. All of these tests determine the extent to which the cancer has spread. Once the stage is determined, doctors can decide on a course of treatment, and can have a better idea of the patient's prognosis.

Unlike other types of lung cancer, the staging of small cell lung cancer is relatively simple. This is because approximately 70% of patients already have metastatic disease when they are diagnosed, and small

WWW.BOOKBAZ.IR

differences in the amount of tumor found in the lungs do not change the prognosis. Small cell lung cancer is usually divided into three stages:

- Limited stage: The cancer is found only in one lung and in lymph nodes close to the lung.
- Extensive stage: The cancer has spread beyond the lungs to other parts of the body.
- Recurrent stage: The cancer has returned following treatment.

Without treatment, small cell lung cancer has the most aggressive clinical course of any type of pulmonary tumor, with median survival from diagnosis of only two to four months. Compared with other cell types of lung cancer, small cell lung cancer has a greater tendency to be widely disseminated by the time of diagnosis, but is much more responsive to **chemotherapy** and irradiation.

Treatment of small cell lung cancer depends on whether the patient has limited, extensive, or recurrent disease. Treatment usually involves radiotherapy and chemotherapy. Surgery is rarely used for this type of lung cancer because the tumor is usually too advanced.

Patients with limited-stage disease are usually treated with chemotherapy. Combinations of two or more drugs have a better effect than treatment with a single drug. Up to 90% of patients with this stage of disease will respond to chemotherapy. The chemotherapy most commonly prescribed is a combination of the drugs etoposide (Vepesid) and cisplatin (Platinol). Combining chemotherapy with chest radiotherapy and/or occasionally surgery has also prolonged survival for limited-stage patients.

In addition to chest radiotherapy, some patients are also treated with **radiation therapy** to the brain, even if no cancer is found there. This treatment, called prophylactic cranial irradiation (PCI), is given to prevent tumors from forming in the brain. The combination of etoposide and cisplatin chemotherapy with chest radiation therapy and PCI has increased the two-year survival of limited-stage small cell lung cancer patients to almost 50%.

Combinations of different chemotherapy agents are also used for treating extensive-stage small cell lung cancer. However, compared with limited-stage patients, the percentage of extensive-stage patients who respond to therapy is lower. Commonly used drug combinations include cyclophosphamide (Cytoxan), doxorubicin (Adriamycin), and vincristine (Oncovin), or etoposide and cisplatin. The addition of radiation therapy to chemotherapy does not improve survival in these patients. However, radiation therapy is used for the palliative (pain relief) treatment of symptoms of metastatic lung cancer, particularly brain and bone tumors.

Patients who have recurrent small cell lung cancer often become resistant to chemotherapy. These patients are treated with palliative radiotherapy. Their doctor may also recommend that they take part in a clinical trial of a new therapy. Patients whose relapse occurs more than six months after their initial treatment, however, may still respond to traditional chemotherapy.

Coping with cancer treatment

The side effects associated with treatment of small cell lung cancer can be severe. Patients should ask their doctor about medications to treat **nausea and vomiting** and other side effects. It is particularly important to eat a nutritious diet and to drink plenty of fluids. In addition, most patients report feeling very tired and should get plenty of rest.

Clinical trials

Most of the improvements in the survival of patients with small cell lung cancer are the result of clinical trials. Ongoing trials are investigating new chemotherapy and radiotherapy regimens. In addition, entirely new types of therapy, such as **gene therapy** and biological therapy, are now being tested. Patients with a lung cancer diagnosis should ask their doctor about participating in a clinical trial.

Alternatives

Many cancer patients have tried using shark cartilage to treat their disease. Shark cartilage is thought to interfere with the tumor's blood supply. A clinical trial using this treatment in lung cancer patients is ongoing. Information on this and other alternative treatments is available on the Internet from the National Center for Complementary and Alternative Medicine.

Patients who decide to try complementary and alternative therapies should tell their doctor. Some of these therapies may interfere with conventional treatment.

Prognosis

Small cell lung cancer is a very aggressive disease. Without treatment, limited-stage patients will survive for three to six months, while extensive-stage patients

will survive six to 12 weeks. However, small cell lung cancer is much more responsive to chemotherapy and radiation therapy than other types of lung cancer. Among patients treated with chemotherapy, 70–90% have a major response to treatment.

Survival in patients responding to therapy is four to five times longer than in patients without treatment. In addition, two years after the start of therapy, about 10% of patients remain free of disease. In general, women tend to have a better prognosis than men. Patients whose disease has spread to the central nervous system or liver have a much worse prognosis. Although the overall survival at five years is 5% to 10%, survival is higher in patients with limited stage disease. About 70% of patients who are disease free after two years do not relapse. After five to 10 disease-free years, relapses are rare.

Prevention

The best way to prevent lung cancer is either not start smoking, or quit smoking. Secondhand smoke from other people's tobacco should also be avoided. Appropriate precautions should be taken when working with substances that can cause cancer (**carcinogens**). Testing houses for the presence of radon gas, and removing asbestos from buildings have also been suggested as preventive strategies.

Lung diseases due to gas or chemical exposure

Definition

Lung diseases due to gas or chemical exposure are conditions that can be acquired from indoor and outdoor air pollution and from ingesting tobacco smoke.

Description

The lungs are susceptible to many airborne poisons and irritants. Mucus present in the airways blocks foreign particles of a certain size; however it is unable to filter all airborne particulates. There are hundreds of substances that can pollute air and harm lungs. Harmful gases and chemicals are just one type of airborne pollutant that can adversely affect the lungs. They include:

- Vehicle exhaust
- Localized pollutants such as arsenic, asbestos, lead, and mercury
- Outdoor pollutants caused by industry and intensified by weather conditions
- Household heating devices, such as wood–burning stoves
- Household chemical products
- Tobacco smoke.

Lungs respond to irritants in four ways, each of which can occur separately or, more often, trigger other responses.

WWW.BOOKBAZ.IR

- Asthma occurs when irritation causes the smooth muscles surrounding the airways to constrict.
- Increased mucus comes from irritated mucus glands lining the airway. Excess mucus clogs the airway and prevents air from circulating.
- Constriction of the lungs results from scarring when supporting tissues are damaged.
- Cancer is caused by certain irritants, such as asbestos and tobacco smoke.

The major categories into which airborne irritants fall are allergic, organic, inorganic, and poisonous, with many agents occupying more than one category.

- Allergic irritants bother only people who are sensitive to them. Cat hair, insect parts, and pollen are common allergens. Chemicals called sulfites, which are widely used as food preservatives, also cause asthma.
- There are many organic dusts that irritate the lungs. Most of them occur on the job and cause occupational lung disease. Grain dust causes silo filler's disease. Cotton and other textile dusts cause byssinosis. Mold spores in hay cause farmer's lung.
- Inorganic dusts and aerosolized chemicals also are found mostly on the job. Classic among them are asbestos and coal dust. Many metals (cadmium, arsenic, chromium, and phosphorus), various other fine particles (cement, mica, rock), acid fumes, ammonia, ozone, and automobile and industrial emissions are part of a very long list.
- While tobacco smoke is a culprit in many smokers, a 2003 report found that those who work in the tobacco industry experience higher incidence of lung disease from tobacco dust in their work environment.
- Most intentional poisons (cyanide, nerve gas) that enter through the lungs pass through and damage other parts of the body. Mustard gas, used during World War I and banned since that time, directly and immediately destroys lungs.
- Tobacco use scars the lungs and causes emphysema and lung cancer.

Causes and symptoms

Lung disease generates three major symptoms: coughing, **wheezing**, and **shortness of breath**. It also predisposes the lungs to infections such as **bronchitis** and **pneumonia**. Cancer is a late effect, requiring prolonged exposure to an irritant. In the case of tobacco, an average of a pack of cigarettes a day for forty years, or two packs a day for twenty years, greatly increases the risk of lung cancer.

KEY TERMS

Allergen—A substance that causes an allergic reaction in those who are sensitive to it.

Asthma—Temporary airway narrowing that causes wheezing and shortness of breath due to allergies.

Bronchitis—Infection in the bronchi (breathing tubes).

Pneumonia—Infection or inflammation in the lung itself.

Diagnosis

A history of exposure combined with a **chest x ray** and lung function studies completes the diagnostic evaluation in most cases. Lung function measures the amount of air breathed in and out, the speed it moves, and the effectiveness of oxygen exchange within the blood. If the cause still is unclear, a **lung biopsy** aids diagnosis.

Treatment

Eliminating the offending irritant and early **antibiotics** for infection are primary. There are many techniques available to remove excess mucus from the lungs. Respiratory therapists are trained in these methods. Finally, there are several machines available to enrich the oxygen content of breathed air.

A surgical treatment called lung reduction volume surgery is emerging as a treatment for certain people over age 65 with severe **emphysema**. It promises substantial return of lung function for selected patients by cutting away diseased parts of the lungs so that healthy tissue functions better. In the fall of 2003, Medicare announced that it would begin paying for the surgery.

Prognosis

Many of these diseases are progressive, because the irritants stay in the lungs forever. Others remain stable after the offensive agents are removed from the environment. Lungs do not heal from destructive damage, but they can clean out infection and excess mucus, and function better.

Prevention

Industrial air filters, adequate ventilation, and respirators in polluted work sites now are mandatory. Tobacco smoke is the world's leading cause of lung disease and many other afflictions. **Smoking** cessation programs are widely available.

Lung perfusion and ventilation scan

Definition

A lung perfusion scan is a nuclear medicine test that produces a picture of blood flow to the lungs. A lung ventilation scan measures the ability of the lungs to take in air and uses radiopharmaceuticals to produce a picture of how air is distributed in the lungs.

Purpose

Lung perfusion scans and lung ventilation scans are usually performed in the same session. They are done to detect pulmonary embolisms, determine how much blood is flowing to lungs, determine which areas of the lungs are capable of ventilation, and assess how well the lungs are functioning after surgery. These tests are called by different names, including perfusion lung scan, aerosol lung scan, radionucleotide ventilation lung scan, ventilation lung scan, xenon lung scan, ventilation/perfusion scanning (VPS), pulmonary scintiphotography, or, most commonly, V/Q scan.

Description

In a lung perfusion scan, a small amount of a protein labeled with a radioisotope is injected into the patient's hand or arm vein. The patient is positioned under a special camera that can detect radioactive material, and a series of photographs are made of the chest. When these images are projected onto a screen (oscilloscope), they show how the radioactive protein has been distributed by the blood in the blood vessels running through the lungs.

In a lung ventilation scan, a mask is placed over the nose and mouth, and the patient is asked to inhale and exhale a combination of air and radioactive gas. Pictures are then taken that show the distribution of the gas in the lungs. Each test takes 15–30 minutes.

Preparation

There is little preparation needed for these tests. The patient may eat and drink normally before the procedure. Tests to check for **pulmonary embolism** are often performed on an emergency basis.

The amount of radioactivity to which a person is exposed during these tests is very low and is not harmful. However, if the patient has had other recent radionuclear tests, it may be necessary to wait until other radiopharmaceuticals have been cleared from the body so that they do not interfere with these tests.

WWW.BOOKBAZ.IR

KEY TERMS

Pulmonary embolism—A blood clot in the arteries that is traveling to the lungs.

Radiopharmaceutical—A radioactive isotope that can be injected or inhaled into the body and then traced for radiologic purposes. For example, the radioactive isotope technetium-99m (Tc-99m) is injected into the body as part of the lung perfusion scan procedure.

Aftercare

No special aftercare is needed. The patient may resume normal activities immediately. The patient may be asked to consume increased amounts of fluids (unless contraindicated because of a medical condition) for one to two days after the procedures to help speed up the elimination of the radioactive material from the body.

Results

Normal results in both tests show an even distribution of radioactive material in all parts of the lungs.

Abnormal

In the lung perfusion scan, an absence of radioactive marker material suggests decreased blood flow to that part of the lung, which could indicate a pulmonary **embolism**. However, **pneumonia**, **emphysema**, or lung tumors can create readings on the lung perfusion scan that falsely suggest a pulmonary embolism is present.

In the lung ventilation scan, absence of marker material when the lung perfusion scan for the area is normal suggests lung disease.

Certain combinations of abnormalities in lung perfusion and ventilation scans suggest pulmonary embolism.

Risks

There are practically no risks associated with these tests.

Lung surgery

Definition

Lung surgery includes a variety of procedures used to diagnose or treat diseases of the lungs. Biopsies are performed to extract a small amount of tissue for diagnosis, resections remove a portion of lung tissue, and other surgeries are aimed at reducing the volume of the lungs, removing cancerous tumors, or improving lung function.

Purpose

The type of lung surgery performed will depend upon the underlying disease or condition, as well as other factors.

- Pneumonectomy usually refers to the removal of a lung, or sometimes one or more lobes (sections containing lung tissue, air sacs, ducts, and respiratory bronchiole). It is most commonly indicated in certain forms and stages of lung cancer.
- Thoracotomy, or surgical incision of the chest wall, is used primarily as a diagnostic tool when other procedures have failed to provide adequate diagnostic information.
- Lobectomy is the term used to describe removal of one lobe of a lung. It is most commonly indicated for lung cancer, but may also be used for cystic fibrosis patients if other treatments have failed.
- Other surgical procedures include segmental resection or wedge resection. A resection is the removal of a part of the lung, often in order to remove a tumor. Wedge resection is removal of a wedge-shaped portion of lung tissue.
- Volume reduction surgery is a newer surgery used to help relieve shortness of breath and increase tolerance for exercise in patients with chronic obstructive pulmonary disease, such as emphysema.
- Other surgeries are continuously improved upon to make biopsy less invasive and surgery more effective, such as video-assisted lobectomy. Other purposes for lung surgery may include severe abscess, areas of

long-term infection, or permanently enlarged or collapsed lung tissue.

Precautions

Thoracotomy should not be performed on patients whose general health status will not tolerate major surgery. Any surgery carries with it risks associated with general **anesthesia** and possibility of infection. Patients whose risk for these complications outweighs benefit may not be considered candidates for lung surgery. Each individual patient's condition will be reviewed prior to the treatment decision.

Description

Lung surgery procedures will vary depending on the underlying cause of the surgical test or intervention. A patient will be placed under general anesthesia during the surgery. An incision is made to examine the lungs. Diseased tissue is removed and may be sent for biopsy. Following the surgery, drainage tubes may be placed in the chest to drain fluids, blood, and air from the chest cavity. Tubes will most likely remain in place for one to two days, depending on the surgery and the patient's condition. The chest cavity, ribs, and skin are closed and the incision will be sutured. Hospital stay averages from three to 10 days.

Pneumonectomy consists of removal of all of one lung. It may often be indicated only when a **lobectomy** does not successfully remove the cancerous or damaged tissue. Thoracotomy consists of reaching the lung tissue through incision and obtaining tissue for a biopsy. The biopsy is used to diagnose or stage cancer, and thoracotomy may be avoided until other less invasive methods have failed. Volume reduction surgery involves incision and removal of those parts of the lung or lungs which are the most destroyed, in order to allow for full function of the remaining lung structure. This procedure is still being studied.

Lobectomy is performed in the same general manner as other lung surgeries, but will involve removal of an entire lobe of the lung. Most patients with Stage I or II **non-small cell lung cancer** will receive this treatment for their disease, or a less extensive resection. Lobectomy may only be performed if a wedge or segmental resection is ineffective, but is generally preferred as treatment for primary lung cancer in any patient who can tolerate the procedure. Wedge and segmental resections are still major surgery, but remove less tissue and may be the first choice for some patients, such as those with Stage I and Stage II non-small cell lung cancer. Patients who do not have enough pulmonary function to undergo a lobectomy will receive a wedge or segmental resection instead. This may lead to a higher recurrence rate of cancer. In general, the surgery method chosen will depend on specific circumstances and consideration of benefit versus risk.

Preparation

Preparation for lung surgery is much like that for any major surgery. Patients will receive instructions from a physician concerning limit of food or water intake prior to the surgery, as well as risks and expected recovery. Patients should continue to follow treatment for the underlying condition, unless instructed otherwise by the physician, and should discuss medications and changes in condition with their physician prior to the surgery.

Aftercare

The chest tube inserted at the end of surgery will remain in place until the lung has fully expanded. Patients will be carefully monitored in the hospital for complications and infection. Deep breathing is recommended to help lessen the risk of **pneumonia** and infection. Breathing exercises will also help expand the lung. After **discharge from the hospital**, the patient may still receive some **pain** or infection-fighting medications and should recover within one to three months of the operation.

Results

Outcome for any lung surgery depends on many factors and the severity of disease. In general, the predicted benefits, which justified the surgery, are normal expected results. Thoracotomy results in a definitive diagnosis in more than 90% of patients. Volume reduction surgery has been shown to result in relief of some symptoms and improvement in quality of life for selected patients with severe **emphysema** and have shown short-term promise.

Mortality from lung surgery improves as procedures move from the more complete pneumonectomy to lobectomy, and the lowest rate for segmental resection.

Risks

Risks of lung surgery follows those of any major surgery involving general anesthesia. These risks include reactions to anesthetics or medications, bleeding, infection, and problems restoring breathing. Lung surgery, in particular, offers the risk of pneumonia and **blood clots**. Thoracotomy, as a biopsy procedure, offers greater risk than most biopsy procedures.

Lung transplantation

Definition

Lung transplantation involves removal of one or both diseased lungs from a patient and replacement of the lungs with healthy organs from a donor. It is also known as pulmonary transplantation. Lung transplantation may refer to single, double, or even heart-lung transplantation. A fourth type, lobar transplantation, refers to the transplantation of a single lobe from a donor's lung to replace a portion of the diseased lung in the recipient. In most cases of lobar transplantation, two lobes from two different donors are used to replace an entire failing lung in the recipient.

Purpose

The purpose of lung transplantation is to replace a lung that no longer functions with a healthy lung. Before the surgeon performs a lung transplantation, he or she should determine the patient's potential for rehabilitated breathing function. Other medical treatments should be attempted before transplantation is considered. Many candidates for this procedure have end-stage fibrotic lung disease, are dependent on **oxygen therapy**, and are likely to die of their disease in 12–18 months.

Demographics

Lung transplantation has been successfully performed since the early 1980s but is still not a common procedure because of the shortage of donor organs. According to the National Institutes of Health (NIH), about 1,800 lung transplants are performed in the United States in an average year, with most patients between the ages of 18 and 65. About 59% of transplant recipients are female. In order to qualify for lung transplantation, a patient must suffer from such severe lung diseases as:

- emphysema
- cystic fibrosis
- pulmonary fibrosis
- pulmonary hypertension
- bronchiectasis
- sarcoidosis
- alpha 1-antitrypsin deficiency
- silicosis

In order to be considered for lung transplantation, patients with **emphysema** or **chronic obstructive pulmonary disease** (COPD) should be under 60 years of age, have a life expectancy without transplantation of two years or less, show progressive deterioration, and possess emotional stability. Young patients with end-stage **silicosis** may be candidates for lung or heart-lung transplantation. Patients with stage III or stage IV **sarcoidosis** with **cor pulmonale** (right-sided **heart failure**) should be considered as early as possible for lung transplantation.

Although current guidelines stipulate that the ideal lung donor is younger than 55 years, recent studies indicate that outcomes involving lungs from donors between the ages of 55 and 64 are nearly identical to those involving lungs transplanted from younger donors. Lungs from donors above 65 years of age, however, are associated with increased mortality in the recipients.

Description

Once a patient has been selected as a possible organ recipient, the process of waiting for a donor organ match begins. The donor organ must meet specific requirements for tissue match in order to reduce the chance of organ rejection. It is estimated that it takes an average of one to two years to receive a suitable donor lung, and the wait is made less predictable by the necessity for tissue match. Patients on a recipient list must be available and ready to come to the hospital immediately when a donor match is found, since the life of a human lung outside the body is brief (4–6 hours).

Prior to 2005, the United Network for Organ Sharing (UNOS) apportioned donor lungs to potential recipients on a first-come, first-served basis. Since 2005, the agency has used a lung allocation score or LAS to assign relative priority to recipients. LAS is a numerical score ranging from 0 to 100, based on the statistical probability that the patient will survive the next year without a transplant coupled with the patient's projected length of survival after the transplant. Factors used to calculate the lAS include the patient's diagnosis, age, **body mass index**, presence or absence of diabetes, need for mechanical ventilation, need for supplemental oxygen, the distance the patient can walk in six minutes, and other factors. The higher the patient's LAS, the higher his or her priority in receiving a donor lung; the average LAS score of patients who receive donor lungs is 40.8.

Single lung transplantation is performed via a standard thoracotomy (incision in the chest wall) with the patient under general **anesthesia**. Cardiopulmonary bypass (diversion of blood flow from the heart) is not always necessary for a single lung transplant. If bypass is necessary, it involves rerouting the blood through tubes to a heart-lung bypass machine. Double lung transplantation involves implanting the lungs as two separate lungs, and cardiopulmonary bypass is usually required. The patient's lung or lungs are removed and the donor lungs are stitched into place. Drainage tubes are inserted into the chest area to help drain fluid, blood, and air out of the chest.

Heart-lung transplants always require the use of cardiopulmonary bypass. An incision is made through the middle of the sternum. The heart, lung, and supporting structures are transplanted into the recipient at the same time.

Preparation

Patients who have diseases or conditions that may make them more susceptible to organ rejection are not selected for lung transplant. This group includes patients who are acutely ill and unstable; have uncontrolled or untreatable pulmonary infection; have significant dysfunction of other organs, particularly the liver, kidney, or central nervous system; or have significant coronary disease or left ventricular dysfunction. Patients who actively smoke cigarettes or are dependent on drugs or alcohol may not be selected. Other contraindications include HIV infection, severe mental illness, **malnutrition**, **obesity**, or a history of noncompliance with medical instructions. There are a variety of protocols that are used to determine if a patient will be placed on a transplant recipient list, and criteria may vary depending on location.

The following diagnostic tests are usually performed to evaluate a patient for lung transplantation:

- An arterial blood gas (ABG) test measures the amount of oxygen that the blood is able to carry to body tissues.
- Pulmonary function tests (PFTs) measure lung volume and the rate of air flow through the lungs. The results indicate the progression of the lung disease.
- A chest x-ray (CXR) takes an internal picture of the chest including the lungs, ribs, heart, and the contours of the major vessels of the chest.
- A computed tomography (CT) scan is taken of horizontal slices of the chest to provide detailed images of the structure of the chest.
- Ventilation perfusion scan (lung scan, V/Q scan) is a test that compares right and left lung function.
- An electrocardiogram (EKG) records the electrical activity of the heart to provide information about the rate and rhythm of the heartbeat and to assess any damage. It is performed by placing electrodes on the chest and one electrode on each of the four limbs.
- An echocardiogram is an ultrasound of the heart and is performed to evaluate the impact of lung disease on the heart. It examines the chambers, valves, aorta, and the wall motion of the heart. Echocardiography also provides information concerning the blood pressure in the pulmonary arteries, which is required to plan the transplantation surgery.
- A bone mineral density scan is performed to evaluate the risk of postoperative osteoporosis or bone fracture.
- Blood samples are required for both routine and specialized testing.

In addition to tests and criteria for selection as a candidate for transplantation, patients are prepared by discussing their procedure, risks, and expected prognosis with their doctor. Patients should continue to follow

KEY TERMS

Alpha 1-antitrypsin deficiency—A genetic disorder characterized by insufficient production of alpha 1-antitrypsin (A1AT), a substance that protects the elasticity of lung tissue. Patients with insufficient A1AT are at high risk of developing emphysema, particularly if they are smokers.

Anesthesia—The loss of feeling or sensation induced by the use of drugs called anesthetics.

Bronchi—Any of the larger air passages of the lungs.

Bronchiectasis—Persistent and progressive dilation of bronchi or bronchioles as a consequence of inflammatory disease such as lung infections, obstructions, tumors, or congenital abnormality.

Bronchioles—The tiny branches of air tubes within the lungs that are the continuation of bronchi and connect to the lung air sacs (alveoli).

Cor pulmonale—Enlargement of the right ventricle of the heart caused by pulmonary hypertension that may result from emphysema or bronchiectasis; eventually, the condition leads to congestive heart failure.

Cystic fibrosis—A generalized disorder of infants, children, and young adults characterized by widespread dysfunction of the exocrine glands and chronic pulmonary disease due to excess mucus production in the respiratory tract.

Emphysema—A pathological accumulation of air in tissues or organs, especially in the lungs.

Immunosuppressive—Relating to the weakening or reducing of the immune system's responses to foreign material; immunosuppressive drugs reduce the immune system's ability to reject a transplanted organ.

Lung allocation score (LAS)—A numerical value from 0 to 100 calculated to determine a patient's priority to receive a donor lung within the United States. The LAS system has been used by the United Network for Organ Sharing (UNOS) since 2005.

Pulmonary—Refers to the respiratory system, or breathing function and system.

Pulmonary fibrosis—Chronic inflammation and progressive formation of fibrous tissue in the pulmonary alveolar walls, with steadily progressive shortness of breath, resulting in death from lack of oxygen or heart failure.

Pulmonary hypertension—Abnormally high blood pressure within the pulmonary artery.

Rejection—Occurs when the body tries to attack a transplanted organ because it reacts to the organ or tissue as a foreign object and produces antibodies to destroy it. Anti-rejection (immunosuppressive) drugs help prevent rejection.

Sarcoidosis—A chronic disease with unknown cause that involves formation of nodules in bones, skin, lymph nodes, and lungs.

Silicosis—A progressive disease that results in impairment of lung function and is caused by inhalation of dust containing silica.

all therapies and medications for treatment of the underlying disease unless otherwise instructed by their physician. Since lung transplantation takes place under general anesthesia, patients are advised not to take food or drink from midnight the night before the surgery.

Aftercare

Transplantation requires a long hospital stay, often three weeks or even longer, and recovery can last up to six months. Careful monitoring will take place in a recovery room immediately following the surgery and in the patient's hospital room. Patients must take immunosuppressive, or anti-rejection, drugs to reduce the risk of rejection of the transplanted organ. The body considers the new organ an invader and will fight its presence. The **anti-rejection drugs** lower the body's immune function in order to improve acceptance of the new organs. These drugs also make the patient more susceptible to infection.

Frequent checkups, including x-ray and blood tests, will be necessary following surgery, probably for a period of several years. Patients are not allowed to drive for the first three months after the procedure, when a physical therapist will evaluate them to determine whether they have adequate hand/eye coordination, ability to move the head well enough to check the rearview mirror, and ability to wear a seat belt without disturbing the incision site.

Results

Demonstration of normal results for lung transplantation patients include adequate lung function and improved quality of life, as well as lack of infection and rejection.

Morbidity and mortality rates

According to the Scientific Registry of Transplant Recipients (SRTR), there were 9,000 Americans living with transplanted lungs as of June 2011 (the last year for which data was available). The survival rate after single-lung transplant was close to 94% at one year, 86% at two years, 67% at three years, and almost 55% at five years.

Risks

Lung transplantation is a complicated and risky procedure, partly because of the organs and systems involved, and also because of the risk of rejection by the recipient's body. Acute rejection most often occurs within the first four months following surgery, but may occur years later. Infection is a substantial risk for organ recipients. An early complication of the surgery can be poor healing of the bronchial and tracheal openings created during the surgery. A late complication and risk is chronic rejection. Rejection can result in inflammation of the bronchial tubes or in late infection from the prolonged use of immunosuppressive drugs to fight rejection.

Luteinizing hormone test

Definition

The luteinizing hormone (LH) test is a test of the blood or urine to measure the level of luteinizing hormone (lutropin). This hormone level is highest immediately before a woman ovulates during her menstrual cycle.

Purpose

The LH test is frequently used to determine the timing of ovulation. Couples who are trying to become pregnant may use information about the timing of ovulation to improve their chance of conception. The LH test and other hormone tests may be used during **infertility** screening to chart a woman's menstrual cycle. It may also be used during preparation for **in vitro fertilization**, to determine when eggs are mature and ready to be removed from the ovary.

Description

Lutenizing hormone is a hormone released by the pituitary gland, a small gland at the base of the brain. The hormone stimulates the ovaries to produce and release eggs each month during the menstrual cycle. The level of LH in the blood is highest before ovulation. This increase in hormone level is sometimes called a "surge." A urine or blood sample can be analyzed by a laboratory for the level of LH present. An LH test may be used as part of an infertility screening to determine if there is a hormonal imbalance that might make it difficult to become pregnant. If fertility drugs are given to stimulate ovulation, an LH test can help determine the best time for sexual intercourse. The LH test may also be used to determine when eggs are mature enough to be surgically removed from the ovary as part of the in vitro fertilization process. LH tests may also aid in the diagnoses of polycystic ovary disease, premature ovarian failure, and **menopause**.

A urine LH detection kit is also available for use at home. These are sometimes called "ovulation tests" and are similar to home **pregnancy** test kits. A sample of the woman's first morning urine is tested with the materials provided in the kit. These home tests are often used by women who want to become pregnant. By monitoring levels of LH and watching for the "surge," they can time sexual intercourse to coincide with ovulation, increasing the chance that the egg will be fertilized.

KEY TERMS

Lutropin—Another term for luteinizing hormone, this hormone stimulates the development and release of the egg from the ovary.

Preparation

If a blood sample is taken, the skin around the vein where the needle will be inserted is swabbed with an antiseptic. No special preparation is necessary for collection of a urine sample.

Aftercare

No special aftercare is required. If the blood is tested, as with any blood sampling, the area where the needle was inserted should be kept clean.

Results

The level of LH in the blood or urine will vary depending on when the sample was taken during the menstrual cycle. LH levels will be highest around the time of ovulation, about halfway between a woman's menstrual periods. Levels will be lower during the rest of the month. Women who have already experienced menopause will normally have lower LH levels.

LH levels that remain low throughout the menstrual cycle may indicate a hormonal imbalance that could prevent ovulation. Additional testing may be required if this test is done as part of an infertility screening.

Risks

There are no significant risks associated with either the blood or urine test for LH.

Lyme disease

Definition

Lyme disease is caused by infection with the spirochete (spiral-shaped) bacterium *Borrelia burgdorferi,* which is transmitted through a bite from a tick of the genus *Ixodes*. Without treatment, Lyme disease can become systemic (body-wide), chronic, and disabling. It is considered a significant **public health** problem in the United States.

Demographics

Lyme disease is endemic to North America, Europe, and Asia, where its incidence reflects the distribution of different species of *Ixodes* vectors. At 30,000 reported cases annually, Lyme disease accounts for more than 90% of all reported vector-borne illnesses in the United States; however, in 2013, the Centers for Disease Control and Prevention (CDC) estimated that its true incidence is ten times higher—300,000 cases. The true incidence of Lyme disease is controversial, since no test is 100% diagnostic, and its symptoms can mimic those of various other disorders. In the United States, Lyme disease is concentrated in the Northeast and upper Midwest, with 95% of 2012 reported cases from 13 states: Maine, New Hampshire, Vermont, Massachusetts, Connecticut, New York, New Jersey, Pennsylvania, Delaware, Maryland, Virginia, Wisconsin, and Minnesota.

The incidence of Lyme disease increased in the United States, with reported cases doubling between 1992 and 2006. The increase was probably due, at least in part, to increasing deer populations, expanding ranges of ticks that feed on deer and mice, and human population migrations into formerly wooded areas. Lyme disease prevalence in Europe may be similar to that in the United States.

Lyme disease affects males and females equally. Although it affects all races, it is most often reported among Caucasians, probably due to their increased exposure to ticks. Disease rates may also be higher in children, because they spend more time outdoors and are less likely to notice ticks on their bodies.

Description

Lyme disease is a vector-borne **zoonosis**, meaning that it is transmitted between animal hosts by a blood-feeding vector and can be transmitted from animals to humans under natural conditions. *B. burgdorferi* is transferred between the bloodstreams of its animal hosts and humans by tick bites. It cannot be transmitted between people or from pets to humans. In the United States, *B. burgdorferi* is carried by ticks of several species in the genus *Ixodes*, especially black-legged ticks, which usually feed on white-footed mice and deer and are often referred to as deer ticks. Lyme disease and similar vector-borne infections caused by other *Borrelia* species are collectively referred as borreliosis.

Adult male deer tick. *(Kent Wood/Photo Researchers, Inc.)*

The majority of Lyme disease cases are successfully treated with oral **antibiotics**. However, some patients continue to experience nonspecific symptoms—such as **pain**, **fatigue**, and joint and muscle aches—following treatment and may be diagnosed with post-treatment Lyme disease or post-Lyme disease syndrome. Other patients, with or without evidence of current or past *B. burgdorferi* infection, have been diagnosed with chronic Lyme disease (CLD). These diagnoses are controversial. While Lyme disease spread by black-legged ticks is endemic to the northeastern United States, a disease with similar symptoms has been widely reported in southern states. Many researchers believe that this similar disease, called Southern tick-associated rash illness (STARI), is spread by the lone star tick, *Amblyomma americanum*, which may carry another *Borrelia* species. Some researchers also believe that another identified bacterium, *Borrelia miyamotoi*, may be responsible for symptoms similar to Lyme disease but with recurring **fever** and without Lyme disease's characteristic bull's eye rash.

Origins

The earliest description of dermatologic symptoms of Lyme disease dates from Europe in 1883. The

WWW.BOOKBAZ.IR

characteristic Lyme disease rash, called erythema migrans (EM), was described in Sweden in 1912. However, the disease was not recognized in the United States until the early 1970s, when a highly unusual cluster of arthritis cases appeared among children in and near the town of Lyme, Connecticut. Most of the affected children lived and played near wooded areas, and their symptoms typically began in summer, at the height of tick season. Several children reported a skin rash that preceded the arthritis and remembered a tick bite at the site of the rash. The signs and symptoms of what came to be called Lyme disease were described by the mid-1970s. In 1981, Willy Burgdorfer and Alan Barbour identified a spirochete bacterium isolated from infected deer ticks as the cause of both EM and Lyme disease. The bacterium was subsequently named *B. burgdorferi* after its discoverer.

Risk factors

People are at risk for Lyme disease if they spend time outdoors in wooded areas where *B. burgdorferi* and the ticks that transmit it are endemic, although the risk depends on the stage of the tick's life cycle. A tick passes through three stages of development—larva, nymph, and adult—that are dependent on a live host for blood meals. In the late summer, larval ticks hatch from eggs laid in the ground and feed once by attaching themselves to small animals and birds. Nymphs feed during the following spring and summer, preferably on white-footed mice, which are the important reservoir of *B. burgdorferi*. Adult ticks feed in the fall, with white-tailed deer their preferred host. Only nymphs and adults can transmit *B. burgdorferi*. Most Lyme disease is contracted in the spring and summer, at the height of human outdoor activity and when nymphs are abundant. Because nymphs are small (less than 0.08 in. or 2 mm), they are difficult to spot on the human body. Although far more adult ticks than nymphs carry *B. burgdorferi*, the adults are much larger and more likely to be noticed and removed within the 24 hours or more of continuous feeding that are needed to transmit the bacteria.

A 2013 study found that forest fragmentation—logging that leaves small wooded parcels intact—increases the incidence of Lyme disease four to five-fold. White-footed mice are most common in these small parcels, which are typical of urban and suburban development and where the mice have no natural predators. In forests larger than about three acres, with more biodiversity, there are other animals for the ticks to feed on that do not carry Lyme disease.

Causes and symptoms

B. burgdorferi enters the skin from the tick salivary glands. Once in the skin, the bacteria may be eliminated by the immune system, invade localized surrounding tissue, or enter the blood and lymphatic system within days or weeks. *B. burgdorferi* can be found in the cerebrospinal fluid (CSF) that bathes the brain and spinal cord within 12 hours after entering the bloodstream. The principal tick vector depends on the region:

- *I. scapularis* in northeastern and upper midwestern United States and Canada
- *I. pacificus* in northwestern United States
- *I. ricinus* in Europe
- *I. persulcatus,* the taiga tick, in Asia

Stage 1

Many people clear the bacteria without ever developing symptoms of disease. The most recognizable symptom is the EM rash around the site of the tick bite, which occurs within three to 30 days of the bite in about 75% of people who develop Lyme disease. EM usually begins as a round, red patch that expands outward and may feel warm or itch. The rash clears from the center out, leaving a bull's-eye effect; in some cases, the center becomes redder instead of clearing. It may look like a bruise on people with dark skin. A rash at the site can also be an allergic reaction to tick saliva rather than infection, particularly if it appears in less than three days and disappears in just a few days.

Although European *B. burgdorferi* strains cause somewhat different symptoms, about 50% of American cases involve flu-like symptoms:

- fatigue
- headache
- chills
- fever
- muscle and joint pain and inflammation, usually in the knee
- lymph node swelling

Stage 2

As untreated *B. burgdorferi* infection spreads through the body, it can produce symptoms weeks, months, or even years after the tick bite, including the following:

- multiple EM lesions
- fatigue
- fever

- severe headache
- numbness
- unexplained pain
- facial paralysis, usually one-sided
- arthritis and other musculoskeletal complaints
- forgetfulness, confusion, mood swings, and irritability
- less commonly, heart abnormalities, such as irregular rhythm (arrhythmias) or cardiac block (slowed heart rate), and eye abnormalities such as swelling of the cornea, tissue, or eye muscles and nerves

Stage 3

The immune response to late-stage infection can cause symptoms in various organs, even though there may be little evidence of the bacteria. Certain genetic factors may make some people more susceptible to long-term arthritis from Lyme disease. These factors appear to be related to autoimmune responses in the joints after eradication of the bacteria. Acrodermatitis chronica atrophicans—a late-stage complication in which the skin on the lower legs or hands becomes paper-thin and inflamed—is seen more frequently in Europe. Late-stage neurologic symptoms are referred to as neuroborreliosis.

Diagnosis

Examination

Early diagnosis and prompt treatment are critical for preventing neurologic complications of Lyme disease; however, a definitive diagnosis can be difficult. It relies on patient information, possible exposure to disease-carrying ticks, clinical judgment, and elimination of other possible causes for symptoms. Lyme disease can mimic other conditions involving multiple body systems, including **chronic fatigue syndrome** and **multiple sclerosis**. Diagnosis can be especially difficult in children who may not effectively describe their symptoms, and fewer than 50% of children realize that they were bitten by a tick.

If individuals are known to have had a tick bite and live in or visited an area where Lyme disease is prevalent, the timing of potential infection can be estimated, and they can be tested for Lyme disease. However, if there is strong reason to suspect Lyme disease—because of a known tick bite in an endemic area and a characteristic rash—they are usually treated without testing. Nevertheless, a tick may go unnoticed, not all patients develop EM, and early symptoms may be nonspecific and flu-like. Arthritis and neurological symptoms may not develop for many months following infection. If there is no evidence of a tick bite or characteristic symptoms, other causes may be ruled out before testing for Lyme disease. Some patients choose to consult so-called Lyme-literate physicians, who are experienced in the many manifestations of long-term Lyme disease.

Tests

Enzyme-linked immunosorbent assays (ELISAs) are used to test the blood for both early and later antibodies against *B. burgdorferi*—immunoglobulin M (IgM) and immunoglobulin G (IgG), respectively.

- If both IgM and IgG tests are negative, they can be repeated in a few weeks.
- If IgM and IgG tests are positive or indeterminate, a western blot test for the antibodies is used to confirm infection.
- If all three tests are positive, the patient likely has Lyme disease.
- If all three tests are negative, antibody levels may be too low to detect, and the tests are repeated in a few weeks.
- If only the IgM test is positive, it is either a false positive or the infection is very recent.
- If the IgG and western blot tests are positive but the IgM test is negative, the patient probably has a later-stage infection or had the infection in the past, since the antibodies remain detectable for life.
- Changes in the levels of IgM and IgG can be used to track disease progression. If the antibody levels rise over time, the patient probably has an active infection.
- It the patient has central nervous system or meningitis-type symptoms, IgM, IgG, and western blot tests may be performed on the CSF.
- Polymerase chain reaction (PCR) is a more sensitive test that detects *B. burgdorferi* DNA. It may be used on synovial fluid collected from an arthritic joint. A positive PCR test indicates recent infection. A negative test indicates either no infection or bacterial DNA levels that are too low to detect.

Other diseases caused by spirochete bacteria, such as **syphilis** and **leptospirosis**, as well as conditions such as HIV, mononucleosis, and various autoimmune diseases, can result in false-positive tests for Lyme disease. Furthermore, about 5–10% of people living in Lyme disease-endemic areas have positive antibody tests with no history of symptoms.

Both the American College of Rheumatology and *Consumer Reports on Health* warn that Lyme disease testing is often performed unnecessarily, because obvious Lyme disease should be treated immediately,

KEY TERMS

Antibodies—Specific proteins produced by the immune system in response to a specific foreign protein or particle called an antigen.

Arthritis—Inflammation of one or more joints.

Autoimmune—Inappropriate immune system responses to the body's own proteins, cells, or tissues.

Borrelia burgdorferi*; *B. burgdorferi—The tick-borne spirochete bacterium that causes Lyme disease.

Borreliosis—Disease caused by bacteria of the genus *Borrelia*, especially Lyme disease.

Cerebrospinal fluid (CSF)—The clear fluid that surrounds and cushions the brain and spinal cord.

Chronic Lyme disease (CLD)—Persistent Lyme disease, post-treatment Lyme disease, or post-Lyme disease syndrome; a controversial diagnosis for various symptoms, including arthritis and neurologic problems, with or without evidence of current or past *B. burgdorferi* infection.

Endemic—Restricted or peculiar to a specific locale or region; especially a disease that is prevalent only in a particular population or area.

Enzyme-linked immunosorbent assay (ELISA)—A highly sensitive technique for detecting and measuring antigens or antibodies.

Erythema migrans (EM)—A red skin rash that is one of the first signs of Lyme disease in the majority of patients.

Immunoglobulin (Ig)—Antibodies; IgM is the first type of immunoglobulin to respond to *B. burgdorferi* infection, followed by IgG.

Ixodes—A genus of ticks that carry *B. burgdorferi* and inject the bacteria into the host while feeding on blood.

Lymph nodes—Small, bean-shaped masses of tissue scattered along the lymphatic system that act as filters and immune monitors, removing fluids, bacteria, and cancer cells that travel through the lymph.

Meningitis—Inflammation of the meninges—the membranes that cover the brain and spinal cord.

Spirochete—Corkscrew-shaped bacteria that cause infections such as Lyme disease and syphilis.

Vector—An animal, such as a tick, that transfers an infectious organism from one host to another while taking a blood meal.

Zoonosis (pl. zoonoses)—An animal disease that can be transmitted to humans under natural conditions, such as Lyme disease.

and it can take up to a month before antibodies are detectable. Testing on the basis of vague symptoms can lead to false positives, misdiagnosis of Lyme disease, and the inappropriate use of antibiotics: Studies have found that almost 80% of people tested for Lyme disease are prescribed antibiotics, regardless of their symptoms or test results. Therefore, testing is recommended only for patients without EM who were definitely exposed to ticks and have other signs of Lyme disease.

Procedures

Very rarely, a **skin biopsy** or other sample is cultured to grow and identify *B. burgdorferi*.

Treatment

Treating Lyme disease early and thoroughly is important because the bacteria can hide for long periods within the body in a clinically latent state. This explains why symptoms can recur in cycles or flare-up after months or years.

Drugs

Initial therapy usually consists of oral antibiotics such as doxycycline or amoxicillin for 14–21 days. If the response is poor, alternative antibiotics, such as cefuroxime axetil, clarithromycin, or azithromycin, are tried. For severe cases and/or nervous system involvement, intravenous antibiotics, such as ceftriaxone, cefotaxime, or penicillin, may be administered for 14–30 days. There are several strains of *B. burgdorferi*, and they do not necessarily respond similarly to different antibiotics. Furthermore, *B. burgdorferi* can hide in places in the body that antibiotics may not reach, and antibiotics are not effective against the dormant bacteria.

Alternatives

Although antibiotic therapy is essential in treating Lyme disease, complementary therapies may help minimize symptoms or improve the immune response.

- Vitamin and nutritional supplements may treat fatigue and susceptibility to infection.

The first sign of Lyme disease is usually an itchy, bull's-eye rash around the site of the tick bite. *(© Scott Camazine/Alamy.)*

- Botanical medicines and homeopathy may help restore health and well-being.
- *Spilanthes* spp. may be active against spirochetes, although this is unproven.
- Chinese medicinal formulae for treating systemic bacterial infections include Wu Wei Xiao Du Yin (Five-Ingredient Decoction to Eliminate Toxin), Yin Hua Jie Du Tang (Honeysuckle Decoction to Relieve Toxicity), and Huang Lian Jie Du Tang (Coptis Decoction to Relieve Toxicity). Inflammation at the site of infection may be treated externally with Yu Lu San (Jade Dew Extract) or Jin Huang San (Golden Yellow Powder).
- Certain Chinese herbs, acupuncture, and ear acupuncture can be used for specific symptoms.
- Honeysuckle flower, forsythia, isatidis, scutellaria, and phellodendron are used for systemic bacterial infections.
- *Echinacea* spp. or goldenseal (*Hydrastis canadensis*) is used to clear infection and boost the immune system.
- Garlic is used for bacterial infections.
- Guided imagery may include visualizing the bacteria in the bloodstream as ticks being killed by a candle flame.

Hydrotherapy can relieve joint pain associated with Lyme disease. Dull, penetrating pain may be relieved by applying a warm compress to the affected area. Sharp, intense pain may be relieved by applying an ice pack.

Probiotics, such as yogurt or *Lactobacillus acidophilus* preparations, either ingested or as a suppository, may help restore a healthy balance of bacteria to the body when long-term antibiotic use has caused **diarrhea** or yeast infection.

Prognosis

Early treatment of Lyme disease with antibiotics is usually successful. Only a small percentage of patients fail to respond or relapse (have recurring symptoms). Most long-term effects of the disease result from misdiagnosis or delayed treatment. Co-infections with other organisms spread by ticks in the same area—such as the parasite *Babesia*, *Ehrlichia* bacteria, or tick-borne encephalitis in Europe—have been involved in most reported fatalities and may be responsible for treatment failures or more severe symptoms.

About 80% of untreated or inadequately treated cases of Lyme disease result in some symptoms of systemic disease. These are usually mild and transient, although chronic, severe, and disabling symptoms are occasionally reported. Although between 15% and 55% of patients report intermittent or chronic symptoms lasting for months or years after appropriate antibiotic treatment, most authorities do not support a diagnosis of a poorly defined post-Lyme disease syndrome and suspect that at least some patients were misdiagnosed with Lyme disease or have coexisting infections or conditions. There is also no evidence that prolonged treatment with antibiotics is effective against these symptoms, which are as variable as fatigue, muscle or joint pain, headaches, **hearing loss**, vertigo, mood and cognitive disturbances, and **insomnia**. A 2013 study failed to find any evidence of an association between Lyme disease and **autism** spectrum disorders.

Prevention

Precautions for avoiding ticks include the following:

- moving leaves and brush away from living quarters
- spraying tick repellent on clothing and exposed skin
- wearing light-colored clothing to maximize tick visibility
- tucking pant legs into socks or boots
- frequently checking children and pets for ticks
- performing daily tick inspections—especially around the groin, underarms, behind the ears, and on the scalp—during spring and summer in high-risk areas
- showering immediately after being outdoors

Blacklegged ticks are slow feeders, and it takes about 36 hours for *B. burgdorferi* to make its way into the body; thus, infection is unlikely if the tick is removed within 24 hours. Ticks should be removed quickly and carefully:

- Calmly grasp the tick as near to the skin as possible, using fine-tipped tweezers.
- Remove the tick by steadily and slowly pulling straight upward with even pressure to minimize the risk of squeezing more bacteria into the bite. Jerking the tick can break off the mouth and cause it to remain in the skin.
- Never try to remove a tick using petroleum jelly, nail polish, alcohol, or a lit match.

- Place the tick in a closed container (for species identification should symptoms develop) or dispose of it by flushing.
- Clean the affected area with rubbing alcohol, iodine scrub, or soap and water.
- See a physician immediately if a rash or patchy discoloration appears within three to 30 days.

An adult vaccine for Lyme disease was available from 1998 until 2002, when it was removed from the U.S. market due to poor demand. Since the vaccine was not long-lasting, vaccinated people are no longer protected. Vaccinated individuals will test positive for Lyme disease antibodies on ELISAs, but an active infection can be detected by western blotting. A vaccine exists for dogs, although veterinarians disagree about its use. As of 2013, some experts were calling for the development of a new human vaccine against Lyme disease.

Lymph node biopsy

Definition

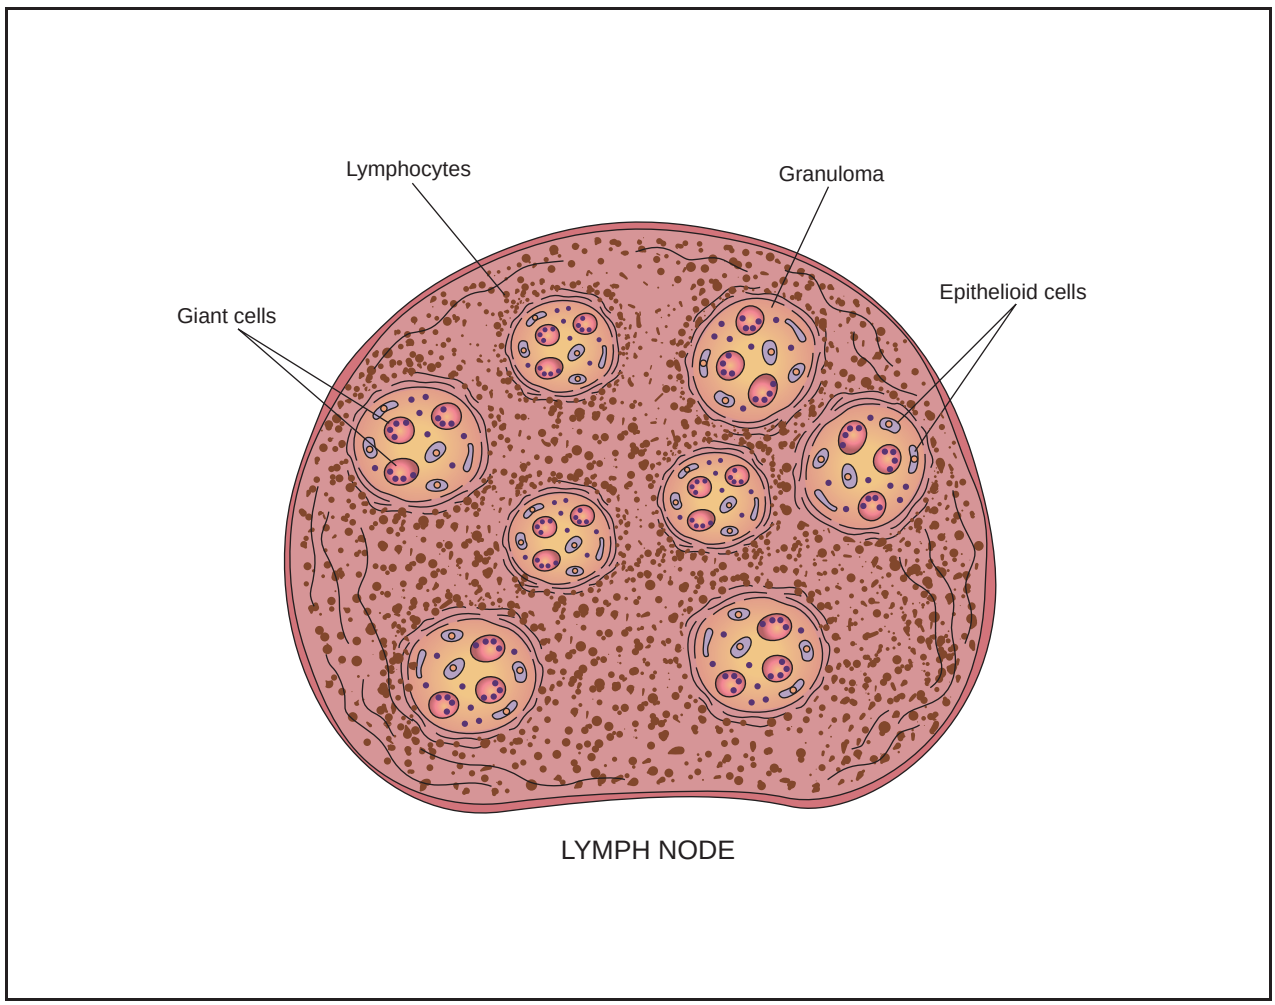
A lymph node biopsy is a procedure in which all or part of a lymph node is removed and examined to determine whether there is cancer within the node, or to determine the cause of **swollen glands** in the head and neck region.

Purpose

The lymph system is the body's primary defense against infection. It consists of the spleen, tonsils, thymus, lymph nodes, lymph vessels, and the clear, slightly yellow fluid called lymph. These components produce and transport white blood cells called lymphocytes and macrophages that rid the body of infection. The lymph system is also involved in the production of antibodies. Antibodies are proteins that fight bacteria, viruses, and other foreign materials that enter the body.

The lymph vessels are similar to veins, only instead of carrying blood as veins do, they circulate lymph to most tissues in the body. The lymph nodes consist of about 600 small, bean-shaped collections of tissue found along the lymph vessel. They produce cells and proteins that fight infection, and they clean and filter lymph. Lymph nodes are sometimes called lymph glands, but they are not true glands. When someone talks about having swollen glands, they are actually referring to lymph nodes.

Normal lymph glands are no larger than 0.5 in. (1.3 cm) in diameter and are difficult to feel. However, lymph nodes can enlarge to greater than 2.5 in. (6 cm)



Lymph node biopsy is a procedure in which a sample of lymph node tissue is removed for laboratory analysis. It is generally performed on an outpatient basis. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

and can become sore. Most often the swelling is caused by an infection, but it can also be caused by cancer.

Cancers can metastasize (spread) through the lymph system from the site of the original tumor to distant parts of the body where secondary tumors are formed. The purpose of a lymph node biopsy is to determine the cause of the swelling and/or to see whether cancer has begun to spread through the lymph system. This information is important in staging the cancer and devising a treatment plan.

Description

There are three kinds of lymph node biopsy. Fine-needle aspiration (FNA) biopsy, often just called needle biopsy, is done when the lymph node of interest is near the surface of the body. A hematologist (a doctor who specializes in blood diseases) usually performs the test. In FNA biopsy, a needle is inserted through the skin and into the lymph node, and a sample of tissue is drawn from the node. This material is preserved and sent to the laboratory for examination.

Advantages of a needle biopsy are that the test is minimally invasive, only a local anesthetic is used, the procedure generally takes less than half an hour, and there is little **pain** afterwards. The disadvantage is that cancer may not be detected in the small sample of cells removed by the needle.

Open lymph node biopsy is a surgical procedure. It is done by a surgeon under general **anesthesia** on lymph nodes in the interior of the body and under local anesthesia on surface lymph nodes where FNA biopsy is considered inadequate. Once there is adequate anesthesia, the surgeon makes a small cut and removes either the entire lymph node or a slice of tissue that is then sent to the laboratory for examination. Results in both kinds of biopsies take one to three days.

Open biopsy can be advantageous in that it is easier to detect and identify the type of cancer in a large piece of tissue. Also, lymph nodes deep in the body can be sampled. Disadvantages include a longer recovery time, soreness at the biopsy site for several days, and the use of deeper anesthesia, increasing the risks to the patient. The procedure is done in a hospital or outpatient surgery center and takes about an hour, with additional time to recover from general anesthesia.

The third type of lymph node biopsy is known as sentinel node biopsy or sentinel node procedure. A sentinel node is the first lymph node or group of nodes reached by a cancer metastasizing from a primary tumor. It is done as part of cancer staging, to determine whether a cancer has spread to a nearby lymph node. Sentinel node biopsy is most commonly done in patients with **breast cancer** or malignant **melanoma**, although it has also been used in patients with **colon cancer**, cancer of the cervix, or **vulvar cancer**.

To perform a sentinel node biopsy, the surgeon injects a radioactive form of technetium near the tumor several hours before the biopsy. About 15 minutes before the biopsy, a blue dye is injected in the same manner. The nodes that take up the dye and radioactive tracer are the sentinel lymph nodes. The surgeon then removes the sentinel nodes and sends them to a pathologist for examination, which takes less than 30 minutes. If cancer is detected in the sentinel node, the surgeon can remove additional lymph nodes. The advantage of the sentinel node procedure is to avoid the unnecessary removal of lymph tissue. This type of biopsy can be done as an outpatient procedure or may require a short hospital stay.

Precautions

Women who are pregnant should inform their doctor before a lymph node biopsy, although **pregnancy** will not affect the results.

Preparation

No particular preparation is necessary for a needle biopsy. For an open biopsy, patients need standard preoperative blood tests and other tests to evaluate general health. The doctor should be informed about any medications (prescription, non-prescription, or herbal) the patient is taking, as well as past bleeding problems or **allergies** to medication or anesthesia.

Aftercare

Little aftercare is needed in a needle biopsy other than a bandage to keep the biopsy site clean. Patients who have general anesthesia for an open biopsy often feel drowsy and tired for several days following the procedure and should not plan to drive home after the biopsy. The incision site must be kept clean and dry, and a follow-up visit to check on healing is usually necessary.

Results

Normal lymph nodes are small and flat. When examined under the microscope, they show no signs of cancer or infection.

KEY TERMS

Lymph nodes—Small bean-shaped organs located throughout the lymphatic system; also called lymph glands. The lymph nodes store special cells that can trap cancer cells or bacteria that are traveling through the body in lymph.

Lymphocytes—Small white blood cells that bear the major responsibility for carrying out the activities of the immune system; they number about 1 trillion.

Malignant—Cancerous. Cells tend to reproduce without normal controls on growth and form tumors or invade other tissues.

Sentinel node—The first lymph node or group of nodes to which cancer cells are likely to spread from a primary tumor.

Spleen—An organ located at the left side of the stomach that acts as a reservoir for blood cells and produces lymphocytes and other products involved in fighting infection.

Thymus—An organ near the base of the neck that produces cells that fight infection. It is at its largest at puberty, then declines in size and function during adult life.

Tonsils—Small masses of tissue at the back of the throat.

Abnormal results

Abnormal lymph nodes are usually enlarged and contain cancerous (malignant) cells and/or show signs of infection.

Risks

There are few risks associated with lymph node biopsy. The main risks are excessive bleeding (usually only in people with blood disorders) and allergic reaction to general anesthesia (rare). Occasionally the biopsy site becomes infected. In a few cases there may be numbness or nerve damage when the lymph node being tested lies close to a nerve. Some patients who have sentinel node biopsies develop an allergic reaction to the blue dye or find their urine or skin temporarily discolored by the dye.

Lymphadenitis

Definition

Lymphadenitis is the inflammation of a lymph node, also sometimes called a lymph gland. The inflammation happens usually in the presence of swollen or enlarged lymph node(s). Because of this symptom, lymphadenitis is commonly called swollen lymph nodes. It is often a complication of a bacterial infection of a wound, although viruses or other disease agents can also cause it. Lymphadenitis may be either one that involving a number of lymph nodes all over the body (what is called generalized

lymphadenitis) or limited to a few nodes in the area of a localized infection (what is termed localized lymphadenitis). Most of the time, the infection of lymph nodes occur in the head and neck, or in the areas of the armpits and groin.

The condition is sometimes accompanied by lymphangitis, which is the inflammation of the lymphatic vessels that connect the lymph nodes. When the disease of a lymph node is caused by an autoimmune disease or a malignancy, in addition to infection, the disease is called lymphadenopathy.

Demographics

Anyone from anywhere in the world can contract lymphadenitis.

Description

Lymphadenitis is marked by swollen lymph nodes that are painful, in most cases, when the doctor touches them. If the lymphadenitis is related to an infected wound, the skin over the nodes may be red and warm to the touch. If the lymphatic vessels are also infected, there will be red streaks extending from the wound in the direction of the lymph nodes. In most cases, the infectious organisms are hemolytic *Streptococci* or *Staphylococci*.

The lymphatic system consists of a vast network or organs, lymph vessels (channels), lymph ducts, and lymph nodes that stretch throughout the human body. The system moves fluid, called lymph, from the tissues to the bloodstream. About 600 lymph nodes exist in the body, with most of them located in the head and neck. They are used to filter the lymph fluid, and to help counter infection, with the use of white blood cells. This extensive network of lymphatic vessels throughout the body and their relation to the lymph nodes helps to explain why bacterial infection of the nodes can spread rapidly to or from other parts of the body. Lymphadenitis in children often occurs in the neck area because these lymph nodes are close to the ears and throat, which are frequent locations of bacterial infections in children.

Causes and symptoms

Streptococcal and staphylococcal bacteria are the most common causes of lymphadenitis, although viruses, protozoa, rickettsiae, fungi, and the **tuberculosis** bacillus can also infect the lymph nodes. Diseases or disorders that involve lymph nodes in specific areas of the body include rabbit **fever** (**tularemia**), **cat-scratch disease**, **lymphogranuloma venereum**, **toxoplasmosis**, **chancroid**, sexually transmitted diseases such as **genital herpes** and **syphilis**, **strep throat**, ear infections, mononucleosis, infected **acne**, infections from **wounds**, dental abscesses, and bubonic **plague**.

In children, **tonsillitis** or bacterial sore throats are the most common causes of lymphadenitis in the neck area. Diseases that involve lymph nodes throughout the body include mononucleosis, **cytomegalovirus infection**, toxoplasmosis, and **brucellosis**. Because lymph nodes play a critical role in fighting off bacteria, viruses, and other foreign invaders within the human body, it is especially important to see a medical professional when these glands become swollen and enlarged.

The early symptoms of lymphadenitis are swelling of the nodes caused by a buildup of tissue fluid and an increased number of white blood cells resulting from the body's response to the infection. The enlargement of the nodes may reach upwards of 0.4 inch (about 1 centimeter). These nodes are also usually tender to the touch. Further developments include fever, often as high as 101–102°F (38–39°C) together with chills, runny nose, **sore throat**, loss of appetite and weight loss, heavy perspiration or night sweats, difficult in swallowing and breathing, a rapid pulse, red and inflamed skin over the swollen gland, and general weakness.

If lymph nodes become swollen throughout the body, then such a situation may indicate the infection is

KEY TERMS

Hemolytic—Able to break down or dissolve red blood cells. The bacteria that cause lymphadenitis are hemolytic.

Hernia—The bulging of a part of the intestine or other organ through its surrounding wall of tissue. Most hernias are in the abdominal cavity. An inguinal hernia is located in the groin area.

Lymph nodes—The gland-like masses of tissue in the lymphatic system that contain lymphocytes. The lymph nodes also filter lymph, which is a clear yellowish tissue fluid that carries lymphocytes and fats throughout the body.

Lymphangitis—Inflammation of the lymphatic vessels. It often occurs together with lymphadenitis.

Septicemia—The presence of bacteria and their toxins in the bloodstream. Septicemia is sometimes called blood poisoning.

Staphylococcus—Any of several species of spherical bacteria that occur in groups of four or irregular clusters. *Staphylococci* frequently cause skin infections.

Streptococcus—Any of several species of bacteria that are spherical in shape and form pairs or chains. *Streptococci* cause scarlet fever, tonsillitis, and pneumonia, and are often involved in lymphadenitis.

one involving mononucleosis, **measles**, or **mumps**; or an immune disorder such as **rheumatoid arthritis**, human **immunodeficiency** virus (HIV), or lupus. In rare cases, the lymph node may grow larger and become hard to the touch—a condition that is rare but may indicate a tumor.

Diagnosis

Physical examination

The diagnosis of lymphadenitis is usually based on a combination of the patient's history, the external symptoms, and laboratory cultures. The doctor will press (palpate) the affected lymph nodes to see if they are sore or tender. Swollen nodes without soreness are often caused by cat-scratch disease. In children, the doctor will need to rule out mumps, tumors in the neck region, and congenital cysts that resemble swollen lymph nodes.

Although lymphadenitis is usually diagnosed in lymph nodes in the neck, arms, or legs, it can also occur in lymph nodes in the chest or abdomen. If the patient has acutely swollen lymph nodes in the groin, the doctor will need to rule out a **hernia** in the groin that has failed to reduce (incarcerated inguinal hernia). Hernias occur in 1% of the general population; 85% of patients with hernias are male.

Laboratory tests

The most significant tests are a **white blood cell count** (WBC) and a **blood culture** to identify the organism. A high proportion of immature white blood cells indicates a bacterial infection. Blood cultures may be positive, most often for a species of staphylococcus or streptococcus. In some cases, the doctor may order a biopsy of the lymph node.

Other tests the doctor may order include an x ray or computerized tomography (CT) scan of the effected area. A **lymph node biopsy** may also be performed so that a small sample of the lymph node can be examined within a laboratory setting.

Treatment

Medications

The medications given for lymphadenitis vary according to the bacterium or virus that is causing it. If the patient also has lymphangitis, he or she will be treated with **antibiotics**, usually penicillin G (Pfizerpen, Pentids), nafcillin (Nafcil, Unipen), or **cephalosporins**. Erythromycin (Eryc, E-Mycin, Erythrocin) is given to patients who are allergic to penicillin.

Over-the-counter **pain** relievers (analgesics/analgesics) may also be used to reduce pain and relieve some of the symptoms. Anti-inflammatory drugs help to reduce inflammation and swelling.

Treatment of swollen lymph nodes where the underlying cause is an immune disorder revolves around treating the underlying condition itself.

If the swollen lymph nodes are caused by different types of cancer (such as lymphoma, leukemia, or other cancers that spread to the lymph nodes), then treatment depends on the recommended treatment for the cancer, such as **chemotherapy**, radiation, or surgery.

If lymphadenitis is not treated properly the formation of abscesses may occur. These abscesses contain fluid, white blood cells, bacteria, dead tissue, and other materials. When such abscesses occur, a doctor usually drains them, along with prescribing antibiotics. In addition, when a bacterial infection occurs

within the lymphatic system, such a condition can lead to **sepsis**, which is a serious infection found within the bloodstream. Hospitalization is usually required because intravenous antibiotics are needed to combat the widespread infection.

Supportive care

Supportive care of lymphadenitis includes resting the affected limb and treating the area with hot, moist compresses.

Surgery

Cellulitis associated with lymphadenitis should *not* be treated surgically because of the risk of spreading the infection. Pus is drained only if there is an **abscess** and usually after the patient has been started on antibiotic treatment. In some cases, a biopsy of an inflamed lymph node is necessary if a diagnosis has not been made and response to treatment has not occurred.

Prognosis

The prognosis for a full recovery is good if the patient is treated promptly with antibiotics. In most cases, the infection can be brought under control in three or four days. However, it may take several weeks, or even months, for the swelling to subside and the area to return to normal. Patients with untreated lymphadenitis may develop blood **poisoning** (septicemia), which is sometimes fatal.

Prevention

Prevention of lymphadenitis depends on prompt treatment of bacterial and viral infections. The practice of living healthy, with special concern on good hygiene, is especially helpful in preventing lymphadenitis, as it is in any infection.

Lymphangiography

Definition

Lymphangiography, or lymph node angiogram, is a test which utilizes x-ray technology, along with the injection of a contrast agent, to view lymphatic circulation and lymph nodes for diagnostic purposes.

Purpose

The lymphatic system is a one way circulation that channels tissue fluid back into the heart. The watery fluid called lymph seeps out of the blood into tissues, and while journeying back to the heart, it picks up germs, cancer cells, and some waste products. Lymph passes through the lymph nodes, which are major arsenals of immune defense that attack germs carried in the lymph. Cancer cells are also subject to attack in lymph nodes.

Cancers of the lymph system, such as Hodgkin's disease and non-Hodgkin's lymphomas, spread throughout the body. Treatment often depends upon finding all the disease and directing radiation to each location. Planning other kinds of treatment, such as surgery or **chemotherapy**, may also require that the full extent of the disease be known.

The lymphatic circulation may become clogged by infection, injury, or several other types of cancer that have spread through lymphatic channels. Swelling, sometimes massive, can result from blocked lymphatics. The most outstanding example of this is the tropical disease **filariasis**, which results in the swelling of the legs termed elephangiasis.

Lymphangiography gives precise information on the extent and location of lymph vessels and lymph nodes. Oftentimes, it is performed to evaluate the extent of a lymphatic cancer. Rarely, it is a tool, which aids surgeons attempting to reconstruct the lymphatics.

Precautions

Lymphangiography should not be performed on patients with dye or shellfish **allergies** or on patients

with chronic lung disease, **kidney disease**, **heart disease**, or **liver disease**.

Description

A lymphangiogram begins by injecting a blue dye into a hand or foot. The lymph system picks up dye, which in turn will highlight the lymph vessels. This process may take a full day. When the lymphatic channel is clearly visible, the radiologist will insert an even tinier needle into that vessel and inject a contrast agent. X rays outline the journey of the contrast agent as it travels to the heart through lymph vessels and nodes.

Preparation

Unless a dye allergy is suspected, no special preparation is need. If an allergy is suspected, a non-ionic contrast agent can be administered instead.

Aftercare

Prior to suture removal seven to 10 days after the procedure, the patient should watch for any sign of infection around the site.

Risks

Lipid **pneumonia** can occur if the contrast agent penetrates the thoracic duct. An allergic reaction to the contrast agent is possible, causing a range of symptoms that can range from innocuous to life threatening.

Lymphedema

Definition

Lymphedema involves blockage of the lymph vessels, with a resulting accumulation of lymphatic fluid in the interstitial tissues of the body.

Demographics

Lymphedema affects approximately 100 million people worldwide, including at least 3 million people in the United States. It is estimated to affect approximately 10–40% of women affected by **breast cancer**. Women who undergo surgery to remove lymph nodes under the arm (axillary area) are at risk for lymphedema, as are those who have radiation in the underarm area.

Description

The lymphatic system consists of lymph vessels and lymph nodes throughout the body. The lymph vessels collect lymphatic fluid, which consists of protein, water, fats, and wastes from cells. The lymph vessels transport the fluid to the lymph nodes, where waste materials and foreign materials are filtered out from the fluid. The fluid is then returned to the blood. When the vessels are damaged or missing, the lymph fluid cannot move freely throughout the system but accumulates. This accumulation of fluid results in abnormal swelling of the arm(s) or leg(s), and occasionally swelling in other parts of the body.

Causes and symptoms

Primary lymphedema is an inherited condition, where the patient is born without lymph vessels and nodes. The swelling associated with primary lymphedema usually occurs during adolescence and affects the foot or calf. A rare form of primary lymphedema, called Milroy's Disease, occurs in **pregnancy**. However, secondary lymphedema, or acquired lymphedema, develops as a result of an injury to the lymph system. Specific causes include surgical treatments for certain types of cancers, especially those cancers that currently require the removal of lymph nodes. Radiation treatment for cancer or for some AIDs-related diseases such as Kaposi-Sarcoma may also result in lymphedema, as radiation may damage or destroy lymph nodes or cause the formation of scar tissue that can interrupt the normal flow of the lymphatic fluid. Specific cancers and their treatment that may result in lymphedema include malignant **melanoma**, breast (in both women and men), gynecological, head

KEY TERMS

Axillary nodes—Lymph nodes found in the armpit that drain the lymph channels from the breast.

Clinical aromatherapy—Aromatherapy is the therapeutic use of plant-derived, aromatic essential oils to promote physical and psychological well-being. It is sometimes used in combination with massage and other therapeutic techniques as part of a holistic treatment approach.

Debulking—General term used for surgeries in which subcutaneous tissue is removed from a lymphodemous limb.

Fibrosis—Formation of fibrous tissue as a reaction or as a repair process; may occur due to treatment and/or disease. in lymphedema condition known as hardening of the limb with resulting restriction of circulatory flow, increased infection, and weeping sores.

Fibrotic—Pertaining to or characterized by fibrosis. In dermatological description, "fibrotic" would be used to describe leathery, bound-down, or thickened, scarred skin.

Interstitial fluid—The fluid between cells in tissues. Referred to as the liquid substance of the body.

Interstitial space—The fluid filled areas that surround the cells of a given tissue; also known as tissue space.

Long-stretch bandages—Specialized bandages, similar to an Ace bandage, that have 100 to 200% stretch.

Low-stretch bandage—Specialized bandages, with 30 to 90% stretch, that are used to obtain the correct compression during the treatment of lymphedema; also known as short-stretch bandages.

Lymph—The almost colorless fluid that bathes body tissues and is found in the lymphatic vessels that drain the tissues of the fluid that filters across the blood vessel walls from blood. Lymph carries antibodies and lymphocytes (white blood cells that help fight infection) that have entered the lymph nodes from the blood.

Lymph nodes—Small bean-shaped organs of the immune system, distributed widely throughout the body and linked by lymphatic vessels. Lymph nodes are garrisons of B, T, and other immune cells.

and neck, prostate, testicular, bladder, and **colon cancer**. Other causes of lymphedema include **trauma** to the lymphatic system from **burns**, **liposuction**, tattooing, injuries, surgery, radiation, **obesity**, heart or circulatory disease, and **multiple sclerosis**. Lymphedema in people at risk may not develop the condition immediately, but develop the condition weeks, months, or even years later. Aircraft travel has been linked to the development of lymphedema in patients after cancer surgery, possible due to the decreased cabin pressure.

In Western countries, one of the most common causes of lymphedema is **mastectomy** with axillary dissection (removal of the breast and underarm lymph tissue for treatment of breast cancer), which may result in lymphedema of the breast, underarm, or arm on the side of the surgery in 10–20% of patients. This occurs because the lymphatic drainage of the arm passes through the axilla (armpit), and tissue in the axilla is removed during the mastectomy. To reduce the risk of developing lymphedema after breast cancer treatment, there is an alternative treatment that avoids axillary lymph node dissection. Sentinel **lymph node biopsy** is a new diagnostic procedure used to determine whether the breast cancer has spread (metastasized) to axillary lymph nodes. A sentinel lymph node biopsy requires the removal of only one to three lymph nodes for close review by a pathologist. If the sentinel nodes do not contain tumor (cancer) cells, this may eliminate the need to remove additional lymph nodes in the axillary area. Early research on this technique indicates that sentinel lymph node biopsy may be associated with less **pain** and fewer complications than standard axillary dissection. Because the procedure is so new, long term data are not yet available. However, there is still a risk for developing lymphedema because of follow-up radiation treatments or **chemotherapy**, which may also damage the lymph nodes.

Symptoms of lymphedema include:

- swelling of an affected limb, which may develop gradually or suddenly
- tightness of the skin and a feeling of heaviness in the affected area
- discomfort or a feeling of "pins and needles" in the affected area
- pitting edema, which can be identified by observing a temporary indentation in the swollen area when pressure is placed on the affected area
- aching in the adjacent shoulder or hip due to the increasing weight of the swelling limb
- tight fitting of a ring, wristwatch, or bracelet, without a gain in weight.

WWW.BOOKBAZ.IR

Lymph System—When sickness or infection invades the body, the immune system is the first line of defense. A big part of that defense is the lymph system. Lymph is carried through the body by lymph vessels that have valves and muscles to help move the fluid. Along the route are lymph nodes that serve as filters for harmful substances. This network of vessels and nodes together is called the lymph system.

Lymphatic fluid—The clear fluid found outside the cells which bathes the tissues. It is collected, filtered, and transported by the lymphatic system from around the tissues to the blood circulatory system. Fluid that collects as a result of lymphedema.

Nail beds—The underlying connective tissue that nourishes the finger and toenails.

Pitting edema—When a swollen area is pressed, the pressure leaves an indentation (pit) that takes time to fill back in.

Sentinel node biopsy—A newer procedure performed in order to determine whether breast cancer has spread to auxiliary (underarm) lymph nodes. A blue radioactive tracer and/or blue dye is injected into the area of the breast tumor. The lymphatic vessels carry the dye or radioactive material, to a "sentinel node." This sentinel node is thought to be the first lymph node receiving fluid from the tumor and the one most likely to contain cancer cells if the cancer has spread. Only if the sentinel node contains cancer cells are more lymph nodes removed.

Skin contracture—A permanent tightening of the skin that prevents normal movement of the associated body part and that can cause permanent deformity. A contracture develops when the normally elastic connective tissues are replaced by inelastic fibrous tissue. This makes the affected area resistant to stretching and prevents normal movement.

Diagnosis

In 90% of the cases, lymphedema is diagnosed through observations, measurements, and symptoms. The remaining 10% require the use of more complex diagnostic tests such as lymphoscintigraphy. Lymphoscintigraphy is a technique in which a radioactive substance that concentrates in the lymphatic vessels is injected into the affected tissue and is mapped using a gamma camera, which images the location of the radioactive tracer. **Magnetic resonance imaging** (MRI), computed tomography (CT) scanning, and duplex **ultrasound** are imaging techniques that are also sometimes used as diagnostic tools for lymphedema.

Persons who have developed lymphedema after cancer treatment should be checked for a diagnosis of possible reoccurrence of cancer, if they experience a sudden increase of swelling, since the tumor growth may be responsible for blocking lymphatic flow.

There are three stages associated with the diagnosis of lymphedema:

- Stage 1 (spontaneously reversible): tissue is still at the pitting stage and soft to the touch. Upon waking in the morning, the limbs or affected areas are of normal or almost normal size.
- Stage 2 (spontaneously irreversible): tissue is nonpitting and no longer soft to the touch, fibrosis begins to form, and the limbs increase in size.
- Stage 3 (lymphostatic elephantiasis): swelling is irreversible and the affected areas are very swollen. The skin hardens and begins to break down, fibrosis is more extensive, and patients may need surgery to remove some of the swollen tissues.

Treatments

Lymphedema is a chronic condition that cannot be cured but can be improved with treatment. There are several major components of a lymphedema treatment program, which should be administered by the health care provider in cooperation with a physical therapist trained in lymphedema treatment. Complete Decongestive Therapy (CDT; also referred to as Complex Decongestive Therapy [CDT] or as Complete Decongestive Physiotherapy [CDP]) combines manual lymph drainage (MLD) with compression techniques and with patient education on self-care needs. The goals of the treatment program are to:

- remove the stagnant lymph fluids out of the tissues
- reduce and help control swelling

- soften fibrotic tissue
- improve the overall health of the patient

However, some lymphedema specialists feel that lymphedema patients with metastatic cancer should not be treated with CDT, to prevent the spreading of the cancer.

MLD was developed in 1932 in Denmark by a doctor and his wife. It was widely used in Europe and now is accepted as a therapy for lymphedema patients in the United States. In MLD a series of rhythmic, light strokes are made in a specific sequence along the lymphatic vessels and the adjoining tissues. These movements remove the lymph fluids from the tissues and return them to the circulatory system, thus reducing swelling in the affected area.

Compression techniques include the use of compression garments, compression aids, and compression bandages. These techniques encourage natural drainage and prevent swelling by supporting tissues in a way that aids in drainage. Compression garments are knit, stretch sleeves or stockings. Compression aids are custom-fitted sleeves, stockings, or pads made of fabric-covered foam. Bandages are an effective and flexible means of compression. They work when the patient is active or is resting and can easily be adjusted to fit changing limb sizes. However, the bandage should be a special type of short-stretch bandage and not the long-stretch bandage that is commonly known as Ace bandages. Only persons who are trained in lymphedema therapy should tape or wrap swollen areas.

Self-care techniques are practiced by the patient or his or her caregiver at home, between visits to the therapist. Self-care techniques include self-massage, skin care to maintain healthy tissue, nutritious diet, and **exercise** to increase lymph flow, increase mobility, and to improve the patient's general health.

Exposure to extreme heat has the potential to increase lymphedema swelling, so an affected person or a person at risk of developing lymphedema should avoid hot tubs, saunas, and steam rooms.

To keep the affected extremities as healthy as possible, a person with lymphedema should keep the swollen areas clean and avoid heavy lifting and pulling as well as avoid any type of trauma, such as cuts, **bruises**, **sunburn** or other burns, injections, **sports injuries**, insect bites, or cat scratches. Some doctors and lymphedema therapists recommend that a person with lymphedema use a preventative course of **antibiotics** when having dental treatment, that is, starting antibiotics several days before the appointment and continuing several days afterwards. A person at risk of developing lymphedema (for example, a woman who has been treated for breast cancer) should also observe the same type of precautions to prevent the development of the condition.

If infections occur, then all treatments for lymphedema should be discontinued while the infection is present, and the infection treated with antibiotics.

Surgery is sometimes used to remove excess tissue ("debulking") if the swollen limb becomes so large and heavy as to interfere with movement.

Exercise is important for a person with lymphedema, but only in moderation. If the extremity starts to ache, the person should lie down and elevate the swollen limb. Recommended exercises include walking, swimming, light aerobics, bike riding, and **yoga**.

Persons with lymphedema should wear a lymphedema alert bracelet or necklace for safety during a medical emergency, explaining the risk of infections. They may also benefit from counseling and membership in support groups to deal with the psychological impact of the disease. Sometimes patients with lymphedema will be denied insurance coverage for treatment; as a result patient advocacy groups in 2005 are attempting to get a law passed through the U.S. Congress guaranteeing insurance coverage for lymphedema. As of 2014, the Lymphedema Coverage Act has government cosponsors and is still in the process of being approved and passed.

Alternatives

The use of clinical **aromatherapy** in conjunction with CDT may improve the quality of life for persons with lymphedema. Clinical aromatherapy involves the use of essential oils to improve the functioning of the immune system, for the immune system is closely associated with the lymphatic system. Also a massage oil comprised of a blend of frankincense, grapefruit, hyssop, and lavender, may be used to soften scarred and fibrotic tissues. Radiation treatments can cause skin **contractures**, which can be helped by massage with a blend of cajeput, frankincense, hyssop, lavender, sage, and tea tree. Radiation can also have adverse effects on the bowel, resulting in poor bowel functioning, scarring, and activity restrictions. Massaging the abdomen with a blend of grapefruit, fennel, helichrysum, lavender, myrrh, and sage may improve intestinal functions. When compression techniques are used, the underlying skin can be treated with a blend of bay laurel, chamomile, geranium, helchrysum, lavender, patchouli, and vetiver in a combination of castor oil, safflower oil, and grapeseed oil as carrier oils. Good skin care is important in preventing infections.

WWW.BOOKBAZ.IR

Body oils that contain cajeput, cypress, lavender, marjoram, and rosewood can be applied after bathing to keep the skin moist and healthy. Finger nail beds can be a portal of entry for infections, so can be kept moist with an essential oil blend of chamomile, geranium, lavender, lemon, sage, tea tree, and ylang ylang.

Prognosis

Lymphedema is a very serious condition. There is no cure for lymphedema and once it develops, it can be a long-term, uncomfortable, and sometimes painful condition requiring daily treatment. When lymphedema is not treated, the protein-rich fluid continues to accumulate, leading to even more swelling and hardening (referred to as fibrosis) of the tissues. This fluid is a good culture medium for bacteria, thus resulting in reoccurring infections when there are injuries to the skin, decrease or loss of functioning of the affected limbs, and skin breakdown. Infections, referred to lymphangitis, can affect the connective tissue under the skin. Repeated infections may result in scarring, which in turn makes the tissue susceptible to more swelling and infection. Over time, these infections result in tissue hardening (i.e., fibrosis), which is a characteristic of advanced chronic lymphedema. In very severe cases, untreated lymphedema may even result in a rare form of lymphatic cancer called lymphangiosarcoma.

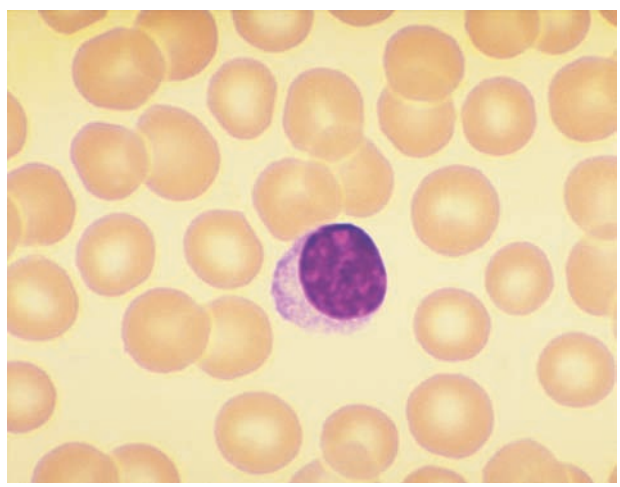
Lymphocyte typing

Definition

Lymphocyte typing focuses on identifying the numbers and relative percentages of lymphocytes in an individual's bloodstream. Lymphocytes, primarily T cells and B cells, are types of white blood cells, the underlying supports of the immune system in the bloodstream.

Purpose

Determining the numbers and relative percentages of T cells and B cells provides information on the state of a person's immune system. By comparing these values to normal numbers and percentages, the presence of disease and the side effects of certain drugs can be revealed. Lymphocyte typing can also show whether a person has been exposed to certain poisonous substances.



A lymphocyte cell. *(© Lester V. Bergman/Corbis.)*

Description

To do a **white blood cell count**, a small amount of blood is drawn from a vein. The total number of white blood cells is calculated, either through microscopic examination of a blood smear or by using automated counting equipment. For a white blood cell count with differential, 100 white blood cells are counted and the proportion of each type is calculated. Since T cells and B cells have similar appearances, a differential can only give the proportion of lymphocytes in the blood, not the proportion of specific lymphocyte types.

For more specific information on B cells and T cells, it is necessary to divide the blood into its separate components. In this procedure, a tube of blood is placed in a centrifuge, a piece of equipment that spins the tube in circles at high speed. The force generated by the spinning causes the various elements in the bloodstream to settle at different levels of the tube.

The lymphocytes are extracted from the tube and treated with special dyes, or stains. Each stain is equipped with an antibody portion that adheres to a specific type of lymphocyte, such as a B cell or a T cell. The stains make the cells visible to an automated counting machine, called a flow cytometer. Based on the number of times the machine detects a particular stain, it can calculate the number of the associated cell type. This procedure can also be used to classify T cells and B cells into their subtypes.

Preparation

If possible, a person should avoid eating a heavy meal within hours of the test or engaging in strenuous **exercise** for the 24 hours preceding the blood test.

Results

In general, normal levels of white blood cells vary slightly by age and gender. Normal values are lower in children under the age of 15 and in young adults between the ages of 20 and 30. After age 30, men have slightly higher levels of white blood cells than women.

Normal adult levels of white blood cells are 4,500–11,000 cells per microliter of blood. Lymphocytes account for approximately 25–45% of the total white blood cell count; the normal range is 1,000–4,800 lymphocytes per microliter of blood. Of the total lymphocytes, 60–80% are T cells and approximately 15% are B cells. (There are two other types of lymphocytes; natural killer and K-type; that constitute a minor proportion of the total lymphocyte numbers.)

KEY TERMS

Immune system—The body's system of defenses against infectious diseases.

Lymphocytosis—A condition in which the number of lymphocytes increases above normal levels.

Lymphopenia—A condition in which the number of lymphocytes falls below normal levels.

White blood cell—A class of cells in the blood that form the foundation of the body's immune system.

Abnormal results

A higher-than-normal level of lymphocytes is called lymphocytosis. Lymphocytosis occurs if a person has a viral, bacterial, or other type of infection. It can also occur with certain blood disorders, such as leukemia.

Lower-than-normal levels of lymphocytes is called lymphopenia. Lymphopenia can be an indicator of certain cancers, bone marrow failure, or immune system deficiency. Medical treatments, such as **chemotherapy** and **radiation therapy**, can also deplete the body's supply of lymphocytes, as can exposure to poisonous substances.

Lymphocytic choriomeningitis

Definition

Lymphocytic choriomeningitis (LCM) is a viral infection of the membranes surrounding the brain and spinal cord and of the cerebrospinal fluid.

Description

Lymphocytic choriomeningitis virus infection is relatively rare and recovery usually occurs spontaneously within a couple of weeks. Many cases are

WWW.BOOKBAZ.IR

probably not even identified because the symptoms range from extremely mild to those resembling severe flu. A few patients develop symptoms of **meningitis**. In some rare cases, the LCM viral infection can spread throughout the central nervous system, and may even be fatal.

Causes and symptoms

LCM is caused by an arenavirus, which is an RNA virus and is a mild cousin in the family containing the much more threatening arenaviruses that cause hemmorrhagic **fever**. Humans acquire LCM virus from infected rodents by coming in contact with the animals or their excretions. Exposure to the virus is not as unlikely to occur as it seems, because the viral hosts can be common house mice and even pets, such as hamsters and chinchillas. Most cases of LCM occur in fall and winter, when mice seek warmth inside dwellings. Food and dust can become contaminated by the excretions of rodents infected with LCM virus. In 1997, French scientists alerted physicians to suspect LCM viral infection in people who had contact with Syrian hamsters.

The symptoms of LCM occur in two phases. The first (prodrome) stage can produce fever, chills, muscle aches, **cough**, and **vomiting**. In the second phase, characteristic meningitis symptoms of **headache**, stiff neck, listlessness, and **nausea and vomiting** may occur. In adults, complications are rare and recovery may even occur before the second phase.

The virus is not spread from person to person, except through **pregnancy**. LCM virus is one of the few viruses that can cross the placenta from mother to child during pregnancy and may be an underrecognized cause of congenital infection in newborns. Infection with cytomegalovirus, *Toxoplasma gondii,*or LCM virus can appear similar enough in infants to be confused when diagnosed. In cases that have been recognized among infants, LCM viral infection has a high mortality rate (about one-third of the babies studied died).

Diagnosis

LCM can be distinguished from bacterial meningitis by the history of prodrome symptoms and the period of time before meningitis symptoms begin, which is about 15–21 days for LCM.

Treatment

No antiviral agents exist for LCM virus. Treatment consists of supporting the patient and treating the symptoms until the infection subsides, generally within a few weeks.

KEY TERMS

Prodrome—Symptom(s) experienced prior to the onset of a disease. For example, visual disturbances may precede and signal the onset of a migraine headache.

Lymphocytopenia

Definition

Lymphocytopenia, also called lymphopenia, is a condition marked by an abnormally low level of lymphocytes in the blood, a condition that raises one's risk of infection. Lymphocytes—a specific type of white blood cell with important functions in the immune system—are produced in the bone's marrow along with other types of blood cells.

Description

Lymphocytes normally account for 20–40% of all white cells in the bloodstream. They help to protect the body from infections caused by viruses or fungi. They also coordinate the activities of other cells in the immune system. In addition, lymphocytes fight cancer and develop into antibody-producing cells that neutralize the effect of foreign substances in the blood.

Lymphocytopenia is the result of abnormalities in the way lymphocytes are produced, make their way through the bloodstream, or are lost or destroyed. This condition can result from congenital or drug-induced decreases in the body's ability to recognize and attack invaders.

There are three types of lymphocytes: B lymphocytes (B cells), T lymphocytes (T cells), and natural killer (NK) cells. All three of these lymphocytes help to

protect the body from infection. When people have lymphocytopenia, they usually have a low number of T lymphocytes. However, one or both of the other types can also be low. A low number of B cells can lead to a decrease in the number of plasma cells, which in turn can result in a decreased production of antibodies. Insufficient numbers of T cells or NK cells cause people to have problems controlling infections caused by bacteria, fungi, parasites, and viruses. Lymphocytopenia is often classified as to which lymphocyte causes the condition; that is, T lymphocytopenia, B lymphocytopenia, and NK lymphocytopenia. When one or more of these lymphocytes is low in number, several reasons are possible:

- insufficient lymphocytes are produced by the body
- although sufficient lymphocytes are produced by the body, they are destroyed
- sufficient lymphocytes are produced by the body, but they are trapped in (rather than pass through) the lymph nodes or spleen
- all of the above reasons can account for lymphocytopenia

People at increased risk for lymphocytopenia include those with the following conditions:

- acquired immune deficiency syndrome (AIDS)
- autoimmune disorders
- blood cancers or other blood diseases
- various inherited diseases or conditions
- receiving steroid therapy or radiation or chemotherapy

Demographics

A normal lymphocyte count for healthy adults is from 1,000 to 4,800 lymphocytes per microliter of blood. For healthy children, the range lies between 3,000 to 9,500 lymphocytes per microliter of blood. When a person has lymphoctyopenia the count is less than 1,000 for adults and less than 3,000 for children.

Causes and symptoms

Lymphocytopenia has a wide range of possible causes:

- AIDS and other viral, bacterial, and fungal infections
- chronic failure of the right ventricle of the heart (this chamber of the heart pumps blood to the lungs)
- Hodgkin's disease and cancers of the lymphatic system
- a leak or rupture in the thoracic duct; the thoracic duct removes lymphatic fluid from the legs and abdomen
- leukemia
- side effects of prescription medications
- malnutrition/undernutrition; diets that are low in protein and overall calorie intake may cause lymphocytopenia
- radiation therapy
- high stress levels
- trauma
- heredity, such as inherited ataxia-telangiectasia, DiGeorge anomaly, and Wiskott-Aldrich syndrome

AIDS and malnutrition/undernutrition are the most common causes of lymphocytopenia.

There can be no symptoms of lymphocytopenia, although **fever** and infection symptoms are the two most commonly noticed symptoms. Lymphocytes constitute only a fraction of the body's white blood cells, and a decline in their number may not produce any symptoms. A patient who has lymphocytopenia may have symptoms of the condition responsible for the depressed level of lymphocytes. Although signs and symptoms are not always present, unusual infections, the same infection that frequently returns, or infections that do not go away may indicate one has lymphocytopenia.

Diagnosis

Lymphocytopenia is most often detected when blood tests are performed to diagnose other diseases. Various blood tests may be used. Three of the frequently used tests are:

- complete blood count with differential: CBC measures red blood cells, white blood cells, and platelets in the blood while the differential part of the test measures the lymphocyte count
- flow cytometry: this test measures the level of the different types of lymphocytes, specifically T cells, B cells, and NK cells
- various tests for underlying conditions: generally, blood, bone marrow, and lymph node tests for blood diseases, human immunodeficiency virus (HIV)/AIDS, immune disorders, and tuberculosis

The condition is also diagnosed with the use of the patient's medical history and a **physical examination**. Because few symptoms are associated with the condition, lymphocytopenia is often diagnosed when testing for other problems or during regular medical checkups. When primary care physicians diagnose the condition or when they think that lymphocytopenia is present, then **infectious disease** specialists or hematologists may be called in for further testing of the immune system or blood, respectively.

WWW.BOOKBAZ.IR

Treatment

Treatment for lymphocytopenia is designed to identify and correct the underlying cause of the condition. If there is no underlying cause and a mild case of the condition is present, then treatment may be unnecessary because the problem will likely disappear on its own. However, if an underlying cause is known, the condition is not mild, or unusual or repeat infections or those that will not go away have occurred, then treatment is needed. The type of treatment used will depend on the condition's cause.

Children who have bacterial infections on a frequent basis may receive immune globulin, which helps the immune system to fight infections. Drug-depressed lymphocyte levels usually return to normal a few days after patients stop taking whatever medication they are already taking.

A deficiency of B lymphocytes, which mature into antibody-producing plasma cells, can result in abnormally low lymphocyte levels. When the number of B lymphocytes is low, patients may be treated with **antibiotics**, antifungal medications, antiviral agents, or a substance containing a high concentration of antibodies (**gamma globulin**) to prevent infection.

It is not usually possible to restore normal lymphocyte levels in AIDS patients. Drugs such as AZT (azidothymidine, sold under the trade name Retrovir), can increase the number of helper T cells, which helps other cells eliminate disease organisms.

Some studies have been conducted to determine if blood and marrow stem cell transplants can be used to treat lymphoctopenia. If successful, these studies may lead to treatments that treat or cure some of the underlying conditions that cause low lymphocyte count.

Prognosis

Very low levels of lymphocytes make patients vulnerable to life-threatening infection. Researchers have investigated the effectiveness of transplanting bone marrow and other cells to restore normal lymphocyte levels. **Gene therapy**, which uses the body's own resources or artificial substances to counter diseases or disorders, is also being evaluated as a treatment for lymphocytopenia.

The prognosis for lymphocytopenia varies depending on its severity and its cause. A severe case of the condition may require several medicines and various treatments.

Prevention

Lymphocytopenia cannot be prevented if it is caused by an inherited condition. However, the condition can be controlled by adhering to the treatment plan devised by the doctor and by taking all medicines at the times and in the amounts prescribed.

If lymphocytopenia is not caused by an inherited condition, then it can be prevented by following these guidelines:

- ask a medical professional for advice on the benefits of getting an annual flu shot and the pneumonia vaccine
- avoid foods that may contain bacteria such as uncooked or undercooked foods
- stay away from people who are ill; avoid large crowds in confined spaces
- minimize infections in the mouth by regularly flossing and brushing teeth; get regular dental care
- wash hands often, especially after handling raw meat

KEY TERMS

Ataxia-telangiectasia (A-T)—Also called Louis-Bar syndrome, a rare neurodegenerative disease that is inherited and can cause severe disability; the term *ataxia* refers to poor coordination and *telangiectasia* relates to small dilated blood vessels.

B lymphocyte—A type of lymphocyte that circulates in the blood and lymph and produces antibodies when it encounters specific antigens. B lymphocytes are also called B cells.

DiGeorge anomaly—Also called DeGeorge syndrome (DGS), 22q11.2 deletion syndrome, velocardio-facial syndrome, and others, a syndrome caused by the deletion of a small part of chromosome 22.

Lymphocyte—A specific type of white blood cell that is important in the production of antibodies.

Wiskott-Aldrich syndrome (WAS)—A rare X-linked recessive disease that involves an abnormal immune system and reduced ability to form blood clots; it is associated with such medical conditions as bloody diarrhea, eczema, immune deficiency, and thrombocytopenia.

Lymphogranuloma venereum

Definition

Lymphogranuloma venereum (LGV) is a sexually transmitted systemic disease (STD) caused by a parasitic organism closely related to certain types of bacteria. It affects the lymph nodes and rectal area, as well as the genitals, in humans. The name comes from two Latin words that mean a swelling of granulation tissue in the lymph nodes resulting from sexual intercourse. Granulation tissue is tissue that forms during wound or ulcer healing that has a rough or lumpy surface.

Description

Although LGV is easily treated in its early stages, it can produce serious complications in its later stages. LGV is most likely to occur among people living in tropical or subtropical countries and among military personnel or tourists in countries or large cities with high rates of the disease. Prostitutes play a major role in carrying and transmitting LGV, as was documented during an outbreak in Florida in the late 1980s. There are about 1000 documented cases of LGV in the United States in an average year.

Causes and symptoms

LGV is caused by *Chlamydia trachomatis*, a globe-shaped parasitic organism that reproduces only inside of living cells. *C. trachomatis* has 17 subtypes and is responsible for a wide range of infections in both men and women; however, only subtypes L1, L2, and L3 cause lymphogranuloma venereum. The parasite has a two-part lifecycle. In the first stage, it is inert and can survive outside of cells. In its second stage, it lacks a cell wall and actively reproduces after gaining entry to a cell. As the chlamydia organism reproduces inside the cell, it pushes the nucleus aside and forms an inclusion that can be identified with tissue staining. LGV differs from other diseases caused by *C. trachomatis* in that it affects the body's lymphatic system and not just the moist tissues of the genital region. In humans, the chlamydia organism is transmitted through vaginal or anal intercourse, oral sex, or contact with fluid from open **ulcers** or infected tissues.

Lymphogranuloma venereum has three stages. In its primary stage, the disease is more likely to be detected in men; it may go unnoticed in women. After an incubation period of four to 30 days, a small painless ulcer or blister develops in the genital area. Second-stage LGV develops between one and six weeks later. In this stage, the infection spreads to the lymphatic system, forming buboes (swellings) in the lymph nodes of the groin area. The buboes often merge, soften, and rupture, forming sinuses and fistulas (hollow passages and ducts) that carry an infectious bloody discharge to the outside of the body. Patients with second-stage LGV may also have **fever**, nausea, headaches, pains in their joints, skin **rashes**, and enlargement of the spleen or liver. Third-stage LGV, which is sometimes called anogenitorectal syndrome, develops in about 25% of patients. In men, this stage is usually seen in homosexuals. Third-stage LGV

WWW.BOOKBAZ.IR

is marked by rectal **pain**, **constipation**, a discharge containing pus or bloody mucus, and the development of strictures (narrowing or tightening of a body passage) in the rectum or vagina.

LGV can have a number of serious complications. *C. trachomatis* infections of any subtype are associated with long-term fertility problems in women. Strictures in the rectum can completely close off the lower bowel, producing eventual rupture of the bowel and inflammation of the abdominal cavity. The patient can develop chronic abscesses or fistulae in the anal area or in the vagina in women. Long-term blockages in the lymph nodes can produce **elephantiasis**, a condition in which the patient's upper legs and groin area become greatly enlarged. Patients with chronic LGV infection have a higher risk of developing cancer in the inflamed areas.

Chronic LGV can be reactivated in patients who become infected with the **AIDS** virus. These patients develop open ulcers in the groin that are difficult to treat.

Diagnosis

The diagnosis of LGV is usually made on the basis of the patient's history, careful examination of the genital area and lymph nodes, and blood tests or cultures to confirm the diagnosis. In the early stages of the disease, the doctor will need to distinguish between LGV and such other STDs as **syphilis** and herpes. If the patient has developed buboes, the doctor will need to rule out **tuberculosis**, **cat-scratch disease**, bubonic **plague**, or **tularemia** (a disease similar to plague that is carried by rabbits and squirrels). If the patient has developed rectal strictures, the doctor will need to rule out tumors or **colitis**.

There are several blood tests that can be used to confirm the diagnosis of LGV. The most commonly used are the complement fixation (CF) test and the microimmunofluorescence (micro-IF) tests. Although the micro-IF test is considered more sensitive than the CF test, it is less widely available. An antibody titer (concentration) of 1:64 or greater on the CF test or 1:512 or greater on the micro-IF test is needed to make the diagnosis of LGV. In some cases, the diagnosis can be made from culturing *C. trachomatis* taken from samples of tissue fluid from ulcers or buboes, or from a tissue sample from the patient's rectum.

Treatment

LGV is treated with oral **antibiotics**, usually tetracycline or doxycycline for 10–20 days, or erythromycin or trimethoprim sulfamethoxazole for 14 days. Pregnant women are usually treated with erythromycin rather than the **tetracyclines**, because this class of medications can harm the fetus.

KEY TERMS

Anogenitorectal syndrome—Another name for third-stage LGV.

Aspiration—A procedure in which pus or other fluid is removed from a body cavity through a hollow needle connected to a syringe.

Bubo—An inflamed swelling inside a lymph node, characteristic of second-stage LGV.

Elephantiasis—Abnormal enlargement of the legs and groin area caused by blockage of the lymphatic system, as a complication of LGV.

Fistula—A passageway formed by a disease or injury that drains fluid from an infected area to the outside or to other parts of the body.

Lymph—A clear yellowish fluid that circulates throughout the body, carrying white blood cells and fats. The system that produces and circulates lymph is called the lymphatic system; it includes lymph vessels, lymph nodes, the thymus gland, and the spleen.

Proctitis—Inflammation of the anus and rectum.

Stricture—An abnormal narrowing or tightening of a body passage. LGV can cause strictures to form in the patient's rectum, or in the vagina of female patients.

Patients who have developed second- and third-stage complications may need surgical treatment. The doctor can treat buboes by withdrawing fluid from them through a hollow needle into a suction syringe. This procedure is called aspiration. Fistulas and abscesses also can be treated surgically. Patients who develop elephantiasis are usually treated by plastic surgeons. Patients with rectal strictures may need surgery to prevent bowel obstruction and rupture into the abdomen.

Prognosis

The prognosis for recovery for most patients is good, with the exception of AIDS patients. Prompt treatment of the early stages of LGV is essential to prevent transmission of the disease as well as fertility problems and other serious complications of the later stages.

Prevention

Prevention of lymphogranuloma venereum has four important aspects:

- Avoidance of casual sexual contacts, particularly with prostitutes, in countries with high rates of the disease.
- Observance of proper safeguards by health professionals. Doctors and other healthcare workers should wear gloves when touching infected areas of the patient's body or handling soiled dressings and other contaminated items. All contaminated materials and instruments should be double-bagged before disposing.
- Tracing and examination of an infected person's recent sexual contacts.
- Monitoring the patient for recurring symptoms for a period of six months after antibiotic treatment.

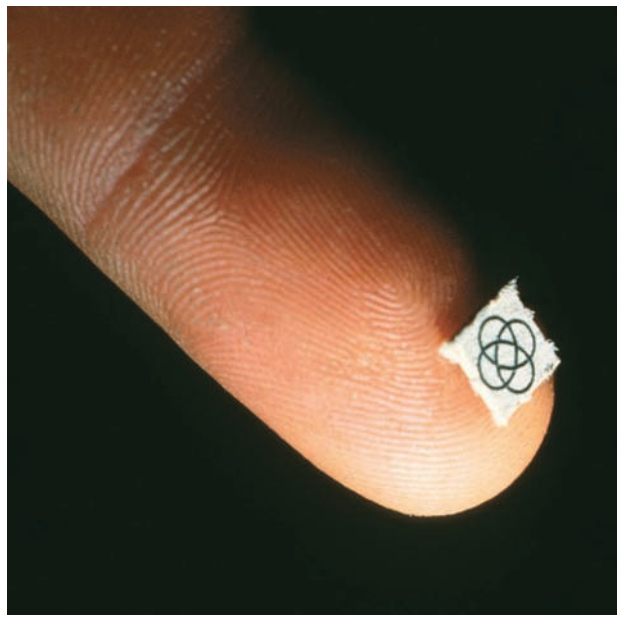
Lysergic acid diethylamide (LSD)

Definition

Lysergic acid diethylamide (LSD), also known as lysergide and informally as acid, belongs to a class of drugs known as hallucinogens, which distort perceptions of reality. LSD, a semisynthetic psychedelic drug, is the most potent mood and perception-altering drug known: Doses as small as 30 micrograms can produce effects lasting six to 12 hours. It is not addictive to humans and does not cause brain damage; however, LSD can cause **anxiety**, **delusions**, and **paranoia**. It is probably best known in the United States as a popular but illegal drug (beginning in 1968) during the 1960s hippy (counterculture) movement. LSD is also commonly known as battery acid, blotter, boomers, cid, doses, dots, golden dragon, heavenly blue, hippie, hits, loony toons, Lucy in the sky with diamonds, microdot, pane, purple heart, sugar cubes, Superman, tabs, trips, window pane, yellow sunshine, zen, and other names.



LSD on blotter paper. *(Custom Medical Stock Photo, Inc.)*

Description

LSD is produced synthetically from ergot, a fungus that grows on rye grass and some grains. This odorless, colorless, and slightly bitter-tasting chemical can be absorbed through the skin but is usually taken orally. It is commonly distributed in small squares of drug-soaked absorbent paper, which are chewed and swallowed. It can also be taken by mouth. The gelatin and liquid forms of LSD can also be placed in the eyes. LSD and other hallucinogens use by secondary school students has decreased since 1998 but has increased among older teens and young adults attending dance clubs, raves (all-night dance parties often held in warehouses and attended by large numbers of young people), and concerts, according to the National Institute on Drug Abuse (NIDA).

LSD alters perceptions by disrupting the action of serotonin, a neurotransmitter. How this happens is unknown. Its effects are most prominent in the cerebral cortex, the brain area involved in mood and perception, and the locus ceruleus, an area in the brain stem where sensory signals converge from all parts of the body. Mescaline and psilocybin, natural hallucinogens resembling LSD, have been used in social and religious rituals for thousands of years.

Effects from LSD begin within an hour and last up to 12 hours. It is absorbed from the intestinal tract, circulates throughout the body and brain, is

WWW.BOOKBAZ.IR

metabolized in the liver, and excreted in the urine within 24 hours. Physical effects of LSD may include loss of appetite, sleeplessness, pupil dilation, **dry mouth**, salivation, **palpitations**, perspiration, nausea, **dizziness**, blurred vision, anxiety, and increases in body temperature, heartbeat, blood pressure, and blood sugar.

The major mental effects of LSD are emotional and sensory. Emotions may quickly shift from euphoria to confusion and despair. Users may simultaneously experience several emotions. Colors, smells, and sounds may be intense. Users may see sounds or smell colors. Time may seem to stand still. Users may have out-of-body sensations or feel as though their bodies have changed shape or merged with another person or object.

Demographics

Swiss scientist Albert Hofmann (1906—2008) first synthesized LSD in 1938. Hofmann synthesized it from ergotamine, a chemical derived from ergot, a grain fungus. In 1947, Sandoz Laboratories introduced LSD commercially under the trademarked Delysid. At the time, LSD was thought to possess several psychiatric uses, including as treatment for **alcoholism**, cluster headaches, and general **pain**. Purported nonmedical uses for the drug include increased creativity and enhanced spirituality. During the 1950s, LSD was used as a mind control agent, both in the military and for civilians. At this time, both mentally ill and healthy patients were documented to be more easily influenced than a control group while using LSD under the direction of medical professionals. LSD was also used experimentally to treat neuroses, narcotic **addiction**, **autism**, alcoholism, terminal cancer, and to study psychoses and **schizophrenia**.

By the 1960s, LSD was one of the drugs of choice for the youth in the counterculture, what is generally called the hippy generation. However, its use prompted U.S. government officials to declare the possession of LSD to be illegal on October 24, 1968. Nearly 30 years after its discovery, the manufacture, possession, sale, and use of LSD were restricted in the United States under the Drug Abuse Control Amendment of 1965. As of 2014, LSD was listed as a Schedule I drug in the United States. According to the U.S. Controlled Substances Act of 1970, LSD is illegal to manufacture, buy, possess, process, or distribute unless a license is procured from the Drug Enforcement Administration (DEA).

Purpose

In the United States, LSD has no accepted medical use, and its manufacture and possession are illegal. Because LSD is classified as a Schedule I drug the DEA states that it has a high probability for abuse, does not have any legitimate medical use in treatment, and there has been a lack of evidence that it can be safely used while under proper medical supervision.

Precautions

Although it is a dangerous drug, LSD is not addictive like cocaine, amphetamines, heroin, alcohol, and nicotine. Its effects are unpredictable and vary with the amount taken and other underlying factors such as personality, mood, expectations, and environment. Users may have enjoyable experiences with some LSD trips and terrifying anxiety and despair with others. Documented deaths from the use of LSD have not been recorded with regards to its chemical toxicity. Most LSD-related deaths stem from panic reactions during intense LSD-triggered illusions.

Side effects

There are two long-term effects associated with LSD use. One is **psychosis**; the other is flashbacks, what is called hallucinogen persisting perception disorder (HPPD). It is unknown how LSD produces these effects. However, they have been seen in chronic hallucinogen users with underlying personality problems and in individuals without a history of psychological disorders. Flashbacks can last from a few seconds to several hours. They generally involve seeing bright flashes, halos, or trails attached to moving objects. LSD-induced psychosis may include dramatic mood swings, loss of cognitive and communication skills, and **hallucinations**.

WebMD states that LSD causes:

- Dilated pupils, increased body temperature, increased heart rate and blood pressure, sweating, loss of appetite, sleeplessness, and dry mouth.
- Changes in sensations and feelings. The person may feel several different emotions at once or rapidly swing from one emotion to another. Also, the person may confuse sensations and feelings, such as hearing colors or seeing sounds.
- Loss of time. The person may feel that time is standing still.
- Delusions and visual hallucinations, if taken in large doses. Delusions are false beliefs, and hallucinations are seeing and hearing things that are not present.

Psychiatric conditions can develop after the use of LSD. WebMD states that these effects include:

- Drug-induced psychosis. Psychosis is a serious condition in which the person has lost the ability to recognize reality, think rationally, or communicate with others. The person may have dramatic mood swings, ranging from being extremely overactive (mania) to severe depression. Psychosis from LSD may last for years.
- Hallucinogen-persisting perception disorder (HPPD). With HPPD, the person has flashbacks in which the person experiences recurrences of some of the sensory distortions that occurred while under the influence of the drug. The person may have the same flashback for years after stopping use of LSD.

According to the Drug Abuse Warning Network (DAWN), the number of LSD-related hospital emergencies is low compared to those related to cocaine, heroin, **marijuana**, **methamphetamine**, and other illicit drugs. One reason for this trend may be that LSD currently sold on the black market is less potent than in the past. LSD dose strengths tend to range from 20 to 80 micrograms in the early 2000s; 100 to 200 micrograms were reported during the 1960s and early 1970s.

Interactions

LSD flashbacks can be spurred by use of drugs such as marijuana. Preliminary evidence suggests serotonin reuptake inhibitors such as Prozac and Zoloft, both antidepressants, may also exacerbate the LSD flashback syndrome. A few seizures have been associated with the use of LSD and lithium in combination. In addition, the use of **monoamine oxidase inhibitors** (MAOIs), a class of drug used for depression, is thought to reduce the effects of LSD.

Results

A 2012 report entitled *Monitoring the Future,* by the NIDA, stated the following for the use of LSD among American youth:

- Eighth graders: 0.3% use during past month; 0.8% past year; 1.3% lifetime
- Tenth graders: 0.5% use during past month; 1.7% past year; 2.6% lifetime
- Twelfth graders: 0.8% use during past month; 2.4% past year; 3.8% lifetime

A similar 2011 NIDA report entitled *National Survey of Drug Use and Health* stated the following for the use of LSD among American adolescents and young adults:

- Ages 12 to 17 years: 0.1% use during past month; 0.6% past year; 0.9% lifetime
- Ages 18 to 25 years: 0.3% use during past month; 1.7% past year; 6.0% lifetime
- Ages 26 years or Older: 0.3% use during past month; 1.7% past year; 6.0% lifetime

According to a 2008 study by the Foundation for a Drug-Free World, as many as 4.2% of Europeans between the ages of 15 and 24 years have used LSD at least once. Of this same age group, over 1% have used LSD in the past year in Bulgaria, the Czech Republic, Estonia, Italy, Latvia, Hungary, and Poland.

Risks

The effect of consuming LSD is unpredictable to its users. Its effect is dependent on the amount taken, the user's mental state (mood, expectations) and physical state (size, condition). Effects from the taking of LSD are usually first felt within 30 to 40 minutes. The LSD experience can last up to 12 hours. LSD can produce adverse psychiatric reactions such as anxiety, delusions, and paranoia.

The short-term risks of taking LSD can be any of the following:

- changes in the sense of hearing, sight, smell, and touch; along with troubles sensing time
- chills, irregular breathing, sweating, trembling hands
- Extreme shifts in behavior and mood and terrifying feelings and thoughts, such as despair and the fear of death and of losing control
- fatigue the day after taking LSD
- increase in blood pressure, blood sugar, and heart rate
- nausea, especially in the first two hours after taking LSD

Long-term problems from taking LSD can also occur. These frequently occur because hallucinogens can cause such medical conditions as depression, **mania**, and schizophrenia. Long-term risks associated with the chronic and/or heavy use of LSD include:

- rapid fluctuation in emotions immediately after using LSD or long after stopping its use
- continuing problems such as anxiety, depression, distorted perception of time, or violent behavior can occur

Macular degeneration

Definition

Macular degeneration is the progressive deterioration of a critical region of the retina called the macula. Age-related macular degeneration (ARMD) is the most common form of macular degeneration. It is also known as age-related maculopathy (ARM), aged macular degeneration, and senile macular degeneration.

Demographics

Macular degeneration is the most common cause of legal blindness in people over 60 and accounts for approximately 11.7% of blindness in the United States or about 10 million Americans. Estimates of the frequency of macular degeneration vary widely by how the disorder is defined by researchers. Some studies estimate that more than 20% of Americans over the age of 60 are affected by the disorder. Other studies, with more rigorous criteria, have found that about 2% of Americans over age 70 and 6% over age 80 have significant macular degeneration.

Caucasians are most likely to be affected by macular degeneration. Individuals of Asian or African descent are less frequently affected, although the incidence has begun to rise in some Asian countries. Individuals of Inuit descent are at a higher risk. Females are slightly more likely to develop macular degeneration than males. People who have light colored eyes tend to have more severe degeneration than those with dark colored eyes. The reason for this is not known. Individuals who smoke, are obese, or have cardiovascular problems are also at increased risk for macular degeneration.

Description

The macula is a 3–5 mm area in the central part of the retina. It is very sensitive to light and is the part of the eye that allows people to see sharp, crisp details. In ARMD, central vision becomes blurry and may be completely lost. Peripheral vision (seeing "out of the corner of one's eye") is not affected, so although people with ARMD may become legally blind (visual acuity of 20/200 or worse), ARMD does not lead to a complete absence of sight. Damage done to the retina by ARMD cannot be repaired. Vision cannot be restored to normal levels, but vision loss can often be slowed, especially if the disease is diagnosed early.

ARMD is subdivided into a dry (atrophic) and a wet (exudative) form. The dry form is more common and accounts for 70–90% of cases of ARMD. It progresses more slowly than the wet form and vision loss is less severe. In the dry form, the macula thins over time as part of the **aging** process and the pigmented retinal epithelium (a dark-colored cell layer at the back of the eye) is gradually lost. Words may appear blurred or hazy, and colors may appear dim or gray.

In the wet form of ARMD, new blood vessels grow underneath the retina and distort the retina. These blood vessels can leak, causing scar tissue to form on the retina. The wet form may cause visual distortion and make straight lines appear wavy. A central blind spot develops. The wet type progresses more rapidly, and vision loss is more pronounced. Treatments are available for some, but not most, cases of the wet form.

Other less common forms of macular degeneration include:

- Cystoid macular degeneration. Loss of vision in the macula due to fluid-filled areas (cysts) in the macular region. This may be a result of other disorders, such as aging, inflammation, or high myopia.
- Diabetic macular degeneration. Deterioration of the macula due to diabetes.
- Senile disciform degeneration (also known as Kuhnt-Junius macular degeneration). A specific and severe type of the wet form of ARMD that involves leaking

blood vessels (hemorrhaging) in the macular region. It usually occurs in people over 40 years old.

Causes and symptoms

Causes

The root cause of ARMD is not known, but scientists have found multiple genes that appear to be associated with the disease and there appears to be an inherited tendency toward developing the disorder. Dry ARMD develops because waste products build up in the retina. The outermost layer of the retina is called the retinal pigment epithelium (RPE). Under this is a layer of blood vessels called the choroid. Nutrients for the retina pass from the choroid blood vessels into the RPE. Waste products from the retina pass in the opposite direction, enter the bloodstream, and are removed. As individuals age, the RPE begins to break down and thin out (atrophy). The waste-disposal system slows down, and waste begins to accumulate faster than it can be removed. Waste buildup causes clumps of yellow pigment, called drusen, to develop under the retina. Drusen are common in people over age 60. Ultimately this failure to dispose of retinal waste causes cells in the macula to become damaged, leading to a loss of central vision.

Some of the same factors that are bad for the heart are thought to contribute to the development of macular degeneration. These risk factors include **smoking** and a diet that is rich in saturated fat. Smokers have a risk of developing ARMD that is approximately 2.4–3 times that of non smokers. Smoking increases the risk of developing wet-type ARMD and may increase the risk of developing dry-type as well. Dietary fat also increases the risk. In one study of older (aged 45–84) Americans, signs of early ARMD were 80% more common in the group that ate the most saturated fat compared to the group that ate the least. Low consumption of **antioxidants**, such as foods rich in **vitamin A**, is associated with a higher risk for developing ARMD. Consumption of moderate amounts of red wine and foods rich in vitamin A is associated with a lower risk. It is generally believed that exposure to ultraviolet (UV) light may contribute to disease development, but this has not been proven.

Wet ARMD develops because the new blood vessels suddenly grow in the choroid layer. These are called choroidal neovascularizations (CNVs). They appear to grow in response to an accumulation of waste or lack of **nutrition** in the retina when the RPE begins to break down. The CNVs leak blood and fluid into the retina (thus the name "wet") causing disruption of the nutrition system and damaging the cells of the macula.

Another less common form of wet ARMD called retinal pigment epithelial detachment occurs when the choroid layer does not grown any CNVs, but fluid from the blood vessels already present leaks and collects under the RPE. Symptoms are the same as for other wet ARMD, but vision deteriorates much more slowly (months or years instead of days or weeks). Eventually new CNVs develop and this form of wet ARMD progresses to the more common form of wet ARMD.

Symptoms

Symptoms of dry and wet ARMD differ. Often dry ARMD shows no symptoms, and neither wet nor dry ARMD cause **pain**. In other cases, individuals with dry ARMD may:

- need more light for reading
- find that colors look paler or washed out
- have difficulty doing detailed work, such as needlepoint or model-making
- have slightly hazy vision
- take longer for their vision to adapt to low lighting
- develop a blurry or blind spot in the center of their field of vision

WWW.BOOKBAZ.IR

The main symptoms of wet ARMD are that straight lines appear distorted and central vision deteriorates rapidly. Sudden onset of symptoms, particularly vision distortion, requires immediate evaluation by an ophthalmologist.

A few people with ARMD develop visual **hallucinations**. They may see patterns, animals, faces, or other objects. This is called Charles Bonnet syndrome, and it is a neurological side effect of ARMD. Although these hallucinations can be upsetting they are not a sign of mental illness.

Diagnosis

To make the diagnosis of macular degeneration, the doctor (an ophthalmologist or a retinal specialist) dilates the pupil with eye drops and examines the interior of the eye, looking at the retina for the presence of yellow bumps called drusen and for gross changes in the macula such as thinning. The doctor also administers a visual field test, looking for blank spots in the central vision. The doctor may call for fluorescein **angiography** (intravenous injection of fluorescent dye followed by visual examination and photography of the back of the eye) to determine if blood vessels in the retina are leaking.

A central visual field test, called an Amsler grid, is usually given to patients who are suspected of having ARMD. It is a grid printed on a sheet of paper (so it is easy to take home). If lines appear wavy or missing when the patient looks at a central dot on the page, the individual should call the doctor right away. This may be an indication of fluid and the onset of wet ARMD. Patients may also be asked to come in for more frequent checkups.

Treatment

ARMD cannot be reversed or cured. The goal of treatment is to slow vision loss. Treatment depends on the type, location, and stage of ARMD. For mild (early-stage) dry ARMD, often the process only involves watchful waiting. Individuals should have regular eye examinations and see their eye care professional immediately if they note any vision changes. They can monitor their vision at home for signs that dry ARMD is converting to wet ARMD by using an Amsler grid, which their physician can provide. This is a simple checkerboard line grid with a dot in the middle. While staring at the dot, individuals with ARMD may notice that some of the lines appear to be missing. If the lines appear wavy, this is a sign that wet ARMD may be developing.

KEY TERMS

Antioxidant—A molecule that prevents oxidation. In the body antioxidants attach to other molecules called free radicals and prevent the free radicals from causing damage to cell walls, DNA, and other parts of the cell.

Drusen—Clumps of pigment that accumulate under the retina when wastes build up faster than they can be removed. Drusen are a sign of dry age-related macular degeneration.

Fovea—A tiny pit in the macula that is responsible for sharp vision.

Macula—The sensitive center of the retina that is responsible for detailed central vision.

Neovascularization—Growth of new capillaries.

Off-label use—Use of a drug for other than the FDA approved purpose. It is legal for physicians to administer drugs for off-label uses, but pharmaceutical companies cannot advertise drugs for such uses.

Photoreceptors—Specialized nerve cells (rods and cones) in the retina that are responsible for vision.

Retina—The light-sensitive membrane at the back of the eye that images are focused on. The retina sends the images to the brain via the optic nerve.

In wet-type ARMD and in senile disciform macular degeneration, new capillaries grow in the macular region and leak. Treatment for wet ARMD, involves procedures and drug therapy. Not every procedure is appropriate for every patient. Many clinical trials are currently underway to test new drugs and treatments for ARMD. Individuals interested in participating in a clinical trial at no cost can find a list of trials currently enrolling new patients at http://www.clinicaltrials.gov.

Photocoagulation is an outpatient procedure in which the doctor uses a laser to burn the CNVs and seal or destroy them so that they will not leak fluid. This procedure is often unsuccessful or produces less than the desired results.

Photodynamic therapy (PDT) involves the injection of the drug verteporfin (Visudyne) followed by laser treatment. The drug accumulates in the CNVs and is activated by laser light. Once activated, it destroys the CNVs. The procedure is not particularly painful. It takes about half an hour and can be done a in the doctor's office.

Drug injections given to stop the growth of CNVs and reduce fluid leakages are called anti-vascular endothelial growth factor (anti-VEGF) medications or anti-angiogenesis drugs. These include:

- pegaptanib (Macugen). This drug is approved for use in wet ARMD. It requires a series of injections.
- ranibizumab (Lucentis). This drug is approved for use in wet ARMD. It destroys new blood vessels and decreases leakage. It has shown some signs of improving vision.
- bevacizumab (Avastin). This drug is approved for treatment of colorectal cancer. Its use in treating ARMD is an off-label use. However, it appears to have some of the benefits of Lucentis.

Kenalog is a steroid drug that is used to treat inflammation. Using it to treat ARMD is an off-label use; however, it appears to be somewhat effective in reducing fluid, especially if used in combination with photodynamic therapy.

Alternatives

A large research study called the Age-Related Eye Disease Study (ARED) found that certain dietary supplements slowed the progression of vision loss by up to 25% in cases of moderate to advanced ARMD. The question of preventing ARMD was not addressed. The ARED supplements include the antioxidants vitamin C, **vitamin E**, beta-carotene (which is converted in the body to vitamin A), and the **minerals** zinc, and copper. Subsequent studies have suggested lutein and zeaxanthin may also be beneficial.

The ARED supplements are to be taken in specific amounts that are often at higher levels than can be acquired through diet alone or than are found in standard multivitamin tablets. Individuals should not begin taking these dietary supplements on their own. They should consult their physician about whether they would benefit from ARED supplementation and review with their physician all medications they are taking in order to prevent harmful interactions.

Home Remedies

Consumption of a diet rich in antioxidants (beta carotene and the mixed carotenoids that are precursors of vitamin A, **vitamins** C and E, selenium, and zinc) or taking antioxidant **nutritional supplements** may help prevent macular degeneration, particularly if started early in life. Good dietary sources of antioxidants include citrus fruits, cauliflower, broccoli, nuts, seeds, orange and yellow vegetables, cherries, blackberries, and blueberries.

Prognosis

The dry form of ARMD is self-limiting and eventually stabilizes. The loss of vision is permanent. About 15% of people with dry ARMD develop wet ARMD. Wet ARMD can progress rapidly and result in legal blindness with only coarse peripheral vision remaining, thus limiting daily activities.

Macular degeneration rarely causes total loss of vision. Peripheral vision is usually retained. Individuals can compensate, to some extent, for the loss of central vision, even though macular degeneration may render them legally blind. Improved lighting and special low-vision aids may help even if sharpness of vision (visual acuity) is poor. Vision aids include special magnifiers that allow the patient to read and telescopic aids for long-distance vision. The use of these visual aids plus the retained peripheral vision usually allows patients to remain independent. Registration as a legally blind person enables patients to obtain special services and considerations.

Prevention

Avoiding the risk factors for macular degeneration may help prevent it. This includes avoiding tobacco smoke and eating a diet low in saturated fat. Some other behaviors that may help reduce the risk of wet-type ARMD are eating a diet rich in green, leafy vegetables and yellow vegetables such as carrots, sweet potatoes, and winter squash; drinking moderate amounts of alcohol, such as one or two glasses of red wine a day; and taking an antioxidant vitamin supplement, especially vitamin A. Some vitamins may be toxic in large doses, so patients should speak with their doctors. Vitamins C and E have not been shown to reduce risk, nor did selenium in one large study. The use of zinc is controversial: Some studies showed a benefit, others showed no benefit, and one actually showed an increased risk of ARMD with increased levels of zinc in the blood. Some doctors suggest that wearing UV-blocking sunglasses reduces risk.

Magnesium imbalance

Definition

A mineral found in the fluid that surrounds cells, magnesium (chemical symbol Mg) is an essential component of more than 300 enzymes that regulate many body functions. Imbalances occur when the blood contains more or less magnesium than it should. When in balance, adults ingest approximately 310 to 420 milligrams of magnesium each day, with differences in daily nutritional requirements based primarily on gender and weight.

Specifically, the dietary reference intake (DRI), from the Institute of Medicine (which is part of the U.S. National Academies), for males and females one to three years of age is 65 milligrams; four to eight years, 110 milligrams; and nine to 13 years, 200 milligrams. For 14 to 18 years of age, the daily DRI is 340 milligrams for males and 300 milligrams for females; 19 to 30 years, 330 milligrams for males and 255 milligrams for females; and 31 years or older, 350 milligrams for males and 265 milligrams for females.

Description

Magnesium is essential for good health. As the fourth most abundant mineral in the human body, it is necessary for the formation and functioning of healthy bones, teeth, muscles, and nerves. The average adult contains about 25 grams of magnesium. About half of all magnesium in the body is located in the bones. However, it is also found in cells within tissues, organs, and blood. It converts food into energy, builds proteins, and is instrumental in maintaining adequate levels of **calcium** in the blood. Magnesium helps prevent cardiovascular disease and irregular heartbeat, reduces the risk of bone loss (**osteoporosis**), and increases an individual's chance of surviving a **heart attack**. It may also help prevent **stroke** and lessen the effects of existing osteoporosis.

Fish, dairy products, leafy green vegetables (such as spinach, broccoli, and peas), legumes, nuts (especially almonds and cashews), seeds (especially sesame seeds), blackstrap molasses, and whole grain cereals (especially buckwheat, brown rice, bulgur, quinoa, and rolled oats) are especially good sources of magnesium. However, varying amounts of this mineral are found in almost all foods. A wide variety of healthy foods helps to assure adequate amounts of magnesium in the body. For instance, about 80 milligrams of magnesium is contained in one-half cup of spinach, whereas 25 milligrams are found in one slice of whole wheat bread, and about 50 milligrams in two tablespoons of peanut butter.

Unhealthy foods, such as highly processed foods (like what is often found in fast food restaurants), contain very low amounts of magnesium because it is usually eliminated from such foods during processing.

Most foods contain only low concentrations of magnesium. In the human body, some is stored in the kidneys, and excess magnesium is excreted in the urine or stools.

Magnesium deficiency (hypomagnesemia) or excess (hypermagnesemia) is rare, but either condition can be serious.

Demographics

Magnesium is the eighth most abundant element on Earth, and the third most frequently found element in seawater. The element also plays an important part in the health of the human body. In the human body, magnesium is the fourth most abundant mineral and affects over 300 biochemical reactions in the body. For instance, magnesium helps to maintain healthy muscles, nerves, and bones, along with a strong heart and immune system. It also helps to manage proper blood sugar levels and blood pressure. An imbalance of magnesium in the human body can occur in anyone regardless of gender, race, or nationality. Perhaps as many as 70% of American adults have a magnesium deficiency.

Causes and symptoms

Hypomagnesemia (too little magnesium) and hypermagnesemi (too much magnesium) can cause a magnesium imbalance. Their symptoms are distinct from one another.

Hypomagnesemia

Magnesium deficiency most often occurs in people who have been fed intravenously for a long time, whose diet does not contain enough magnesium, or who are unable to absorb and excrete the mineral properly.

Secreting too much aldosterone (the hormone that regulates the body's salt-fluid balance), antidiuretic hormone (abbreviated ADH and also called vasoressin, a hormone that inhibits urine production), or thyroid hormone can cause hypomagnesemia.

Other factors associated with hypomagnesemia include:

- loss of body fluids as a result of stomach suctioning or chronic diarrhea
- cisplatin (a chemotherapy drug, also called cisplatiunum and cis-diamminedichloridoplatinum(II) [CDDP])
- long-term diuretic therapy
- hypercalcemia (abnormally high levels of calcium in the blood)
- diabetic acidosis (a condition in which the body's tissues have a higher-than-normal acid content)
- complications of bowel surgery
- chronic alcoholism
- malnutrition
- starvation
- severe dehydration

People who have hypomagnesemia usually experience loss of weight and appetite, bloating, and muscle **pain**, and they pass stools that have a high fat content. In addition, they may be listless, disoriented, confused, and irritable. Other symptoms of hypomagnesemia are:

- nausea
- vomiting
- muscle weakness, along with stiffness, aches, cramps, and spasms
- tremors
- irregular heartbeat, angina
- back pain
- headaches
- joint and bone pain
- constipation
- nervousness
- delusions and hallucinations
- leg and foot cramps
- muscle twitches (spasms)
- changes in blood pressure

Severe magnesium deficiency can cause seizures, especially in children. It can also contribute to cardiovascular disease, osteoporosis, high blood pressure, migraine headaches, diabetes, **anxiety disorders**, and other such diseases.

Neonatal hypomagnesemia can occur in premature babies and in infants who have genetic parathyroid disorders or who have had blood transfusions. This condition also occurs in babies born to magnesium-deficient mothers or those who have any of the following:

- diabetes mellitus
- hyperparathyroidism (overactive parathyroid glands)
- toxemia (a pregnancy-related condition characterized by high blood pressure and fluid retention)

Hypermagnesemia

Hypermagnesemia is most common in patients whose kidneys cannot excrete the magnesium they

WWW.BOOKBAZ.IR

derive from food or take as medication. This condition can also develop in patients who take magnesium salts or in healthy people who use large quantities of magnesium-containing **antacids**, **laxatives**, or **analgesics** (pain relievers).

Magnesium **poisoning** can cause severe **diarrhea** in young people and mask the symptoms of other illnesses. Very high doses can lead to **coma**. The risk of complications of magnesium poisoning is greatest for the following groups:

- elderly people with inefficient kidney function
- patients with kidney problems or intestinal disorders
- people who use antihistamines, muscle relaxants, or narcotics

Severe **dehydration** or an overdose of supplements taken to counteract hypomagnesemia can also cause this condition.

People who have hypermagnesemia may feel flushed and drowsy, perspire heavily, and have diarrhea. Breathing becomes shallow, reflexes diminish, and the patient becomes unresponsive. Muscle weakness and **hallucinations** are common. The patient's heartbeat slows dramatically and blood pressure plummets. Extreme toxicity, which can lead to coma and cardiac arrest, can be fatal.

Diagnosis

Blood tests are often used by physicians and other medical professionals to measure magnesium levels. The magnesium test is used to measure the level of magnesium in the blood, and sometimes in the urine. A blood sample is usually drawn from a vein in the arm. People need to follow the instructions given by the doctor because **fasting** is often required beforehand. Sometimes, a timed urine collection is used, which requires a sample over a 24-hour period. For instance, low levels of magnesium in the blood can indicate that one is not consuming or absorbing enough magnesium or excreting too much of the element. In women, magnesium levels decrease during the second and third trimesters of **pregnancy**. When symptoms such as weakness, irritability, cardiac arrhythmia, nausea, and/or diarrhea that may be due to too much or too little magnesium; when individuals have abnormal calcium or potassium levels, they need to make an appointment to see a medical professional.

In addition, abnormal magnesium levels are often diagnosed by symptoms. As such, it is important to describe all unusual symptoms that one may be having to a medical professional during the diagnosis phase of an office visit.

KEY TERMS

Hypermagnesemia—An abnormally high concentration of magnesium in the blood.

Hypomagnesemia—An abnormally low concentration of magnesium in the blood.

Treatment

The goal of treatment is to identify and correct the cause of the imbalance. Oral magnesium supplements or injections are usually prescribed to correct mild magnesium deficiency. If the deficiency is more severe or does not respond to treatment, magnesium sulfate or magnesium chloride may be administered intravenously.

Doctors usually prescribe **diuretics** (urine-producing drugs) for patients with hypermagnesemia and advise them to drink more fluids to flush the excess mineral from the body. Patients whose magnesium levels are extremely high may need mechanical support to breathe and to circulate blood throughout their bodies.

Intravenously administered calcium gluconate may reverse damage caused by excess magnesium. Intravenous furosemide (Lasix) or ethacrynic acid (Edecrin) can increase magnesium excretion in patients who obtain enough fluids and whose kidneys are functioning properly.

In an emergency, dialysis can provide temporary relief for patients whose kidney function is poor or who are unable to excrete excess **minerals**.

Prognosis

Because imbalances may recur if the underlying condition is not eliminated, monitoring of magnesium levels should continue after treatment has been completed.

Prevention

Most people consume adequate amounts of magnesium in the food they eat. Eating fruits, vegetables, and whole grains is important to maintain healthy levels of magnesium in the body. Dietary supplements can be used safely but should only be used under a doctor's care and supervision.

Magnetic field therapy

Definition

Magnetic therapy is the use of magnets to relieve **pain** in various areas of the body.

Purpose

Some of the benefits that magnetic therapy claims to provide include:

- pain relief
- reduction of swelling
- improved tissue alkalinization
- more restful sleep
- increased tissue oxygenation
- relief of stress
- increased levels of cellular oxygen
- improved blood circulation
- anti-infective activity

Description

Origins

Magnetic therapy dates as far back as the ancient Egyptians. Magnets have long been believed to have healing powers associated with muscle pain and stiffness. Chinese healers as early as 200 B.C. were said to use magnetic lodestones on the body to correct unhealthy imbalances in the flow of *qi,* or energy. The ancient Chinese medical text known as *The Yellow Emperor's Canon of Internal Medicine* describes this procedure. The *Vedas*, or ancient Hindu scriptures, also mention the treatment of diseases with lodestones. The word *lodestone* or leading stone, comes from the use of these stones as compasses. The word "magnet" probably stems from the Greek *Magnes lithos*, or "stone from Magnesia," a region of Greece rich in magnetic stones. The Greek phrase later became *magneta* in Latin.

Sir William Gilbert's 1600 treatise, *De Magnete*, was the first scholarly attempt to explain the nature of magnetism and how it differed from the attractive force of static electricity. Gilbert allegedly used magnets to relieve the arthritic pains of Queen Elizabeth I. Contemporary American interest in magnetic therapy began in the 1990s, as several professional golfers and football players offered testimony that the devices seemed to cure their nagging aches and injuries.

Many centuries ago, Earth was surrounded by a much stronger magnetic field than surrounds it today. Over the past century and a half, scientists have been studying the decline of this magnetic field and the effects it has had on human health. When the first cosmonauts and astronauts went into space, physicians noted that they experienced bone **calcium** loss and **muscle cramps** when they were out of Earth's magnetic field for any extended period of time. After this discovery was made, artificial magnetic fields were placed in the space capsules.

There are two theories that are used to explain magnetic therapy. One theory maintains that magnets produce a slight electrical current. When magnets are applied to a painful area of the body, the nerves in that area are stimulated, thus releasing the body's natural painkillers. The other theory maintains that when

WWW.BOOKBAZ.IR

magnets are applied to a painful area of the body, all cells in that area react in such a way as to increase blood circulation, ion exchange, and oxygen flow to the area. Magnetic fields attract and repel charged particles in the bloodstream, increasing blood flow and producing heat. Increased oxygen in the tissues and blood stream is thought to make a considerable difference in the speed of healing.

Preparations

There are no special preparations for using magnetic therapy other than purchasing a product that is specific for the painful area being treated. Products available in a range of prices include necklaces and bracelets; knee, back, shoulder and wrist braces; mattress pads; gloves; shoe inserts; and more.

Precautions

The primary precaution involved with magnetic therapy is to recognize the expense of this therapy. The use of magnets for therapy has become big business. They can be found in mail–order catalogs and stores ranging from upscale department stores to specialty stores. As is the case with many popular self-administered therapies, many far–fetched claims are being made about the effectiveness of magnetic therapy. Consumers should adopt a "let the buyer beware" approach to magnetic therapy. Persons who are interested in this form of treatment should try out a small, inexpensive item to see if it works for them before investing in the more expensive products.

Side effects

There are very few side effects from using magnetic therapy. Generally, patients using this therapy find that it either works for them or it does not. Patients using transcranial magnetic stimulation for the treatment of depression reported mild **headache** as their only side effect.

Research and general acceptance

Magnetic therapy is becoming more and more widely accepted as an alternative method of pain relief. Since the late 1950s, hundreds of studies have demonstrated the effectiveness of magnetic therapy. In 1997, a group of physicians at Baylor College of Medicine in Houston, Texas studied the use of magnetic therapy in 50 patients who had developed **polio** earlier in life. These patients had muscle and joint pain that standard treatments failed to manage. In this study, 29 of the patients wore a magnet taped over a trouble spot, and 21 others wore a nonmagnetic device. Neither the researchers nor the patients were told which treatment they were receiving (magnetic or nonmagnetic). As is the case with most studies involving a placebo, some of the patients responded to the nonmagnetic therapy, but 75% of those using the magnetic therapy reported feeling much better.

KEY TERMS

Fibromyalgia—A chronic syndrome characterized by fatigue, widespread muscular pain, and pain at specific points on the body.

Lodestone—A variety of magnetite that possesses magnetic polarity.

Transcranial magnetic stimulation—A procedure used to treat patients with depression.

In another study at New York Medical College in Valhalla, New York, a neurologist tested magnetic therapy on a group of 19 men and women complaining of moderate to severe burning, tingling, or numbness in their feet. Their problems were caused by diabetes or other conditions present such as **alcoholism**. This group of patients wore a magnetic insole inside one of their socks or shoes for 24 hours a day over a two-month period, except while bathing. They wore a non-magnetic insert in their other sock or shoe. Then for two months they wore magnetic inserts on both feet. By the end of the study, nine out of ten of the diabetic patients reported relief, while only three of nine non-diabetic patients reported relief. The neurologist in charge of the study believed that this study opens the door to additional research into magnetic therapy for diabetic patients.

A federally funded study began at the University of Virginia. This study intended to evaluate the effectiveness of magnetic mattress pads in easing the muscle pain, stiffness and **fatigue** associated with **fibromyalgia**.

Magnetic therapy is offered for the treatment of patients suffering from depression. A procedure called transcranial magnetic stimulation (TMS) has been beneficial for patients with depression when standard depression treatments, such as anti–depression medication and therapy, have not worked. Patients undergoing TMS have experienced a lower relapse rate than those using **electroconvulsive therapy**. Unlike electroconvulsive therapy, patients using magnetic therapy have not suffered from seizures, memory lapses, or impaired thinking. Mayo Clinic, a large teaching hospital in Rochester, Minnesota,

has offered TMS as a treatment option for depression since 2002.

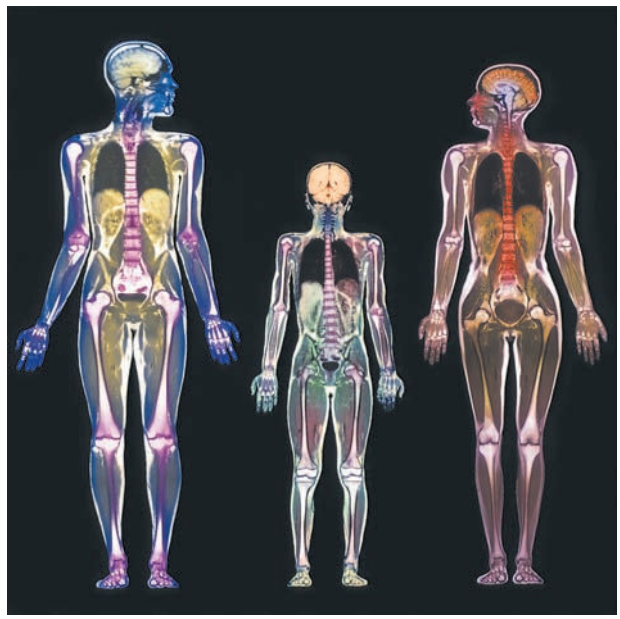
Magnetic resonance imaging

Definition

Magnetic resonance imaging (MRI) is a versatile medical imaging technology that uses strong magnets and pulses of radio waves to manipulate the natural magnetic properties of the body to produce highly refined images on the body's interior without surgery. MRI makes better images of organs and soft tissues than other scanning technologies. It is particularly useful for imaging the brain and spine, as well as the soft tissues of joints and the interior structure of bones. The entire body is visible to the technique, which poses few known health risks.



MRI body scans of a man, woman, and child. *(Simon Fraser/ Photo Researchers, Inc.)*

Purpose

MRI was developed in the 1980s. Subsequent additions to MRI technology are magnetic resonance **angiography** (MRA) and spectroscopy (MRS). MRA was developed to study blood flow, while MRS can identify the chemical composition of diseased tissue and produce color images of brain function. The many advantages of MRI include:

- Detail. MRI creates precise images of the body based on the varying proportions of magnetic elements in different tissues. Very minor fluctuations in chemical composition can be determined. MRI images have greater natural contrast than standard x rays, computed tomography (CT) scans, or ultrasounds, all of which depend on the differing physical properties of tissues. This sensitivity lets MRI distinguish fine variations in tissues deep within the body. It is also particularly useful for spotting diseased tissues (tumors and other lesions) early in their development. Often, doctors prescribe an MRI scan to more fully investigate earlier findings of other imaging techniques.
- Scope. The entire body can be scanned, from head to toe and from the skin to the deepest recesses of the brain. Moreover, MRI scans are not obstructed by bone, gas, or body waste, which can hinder other

WWW.BOOKBAZ.IR

imaging techniques. Nevertheless, MRI scans can be degraded by motion such as breathing, heartbeat, and normal bowel activity. The MRI process produces cross-sectional images of the body that are as sharp in the middle as on the edges, even of the brain through the skull. A close series of these two-dimensional images can provide a three-dimensional view of a targeted area.

- Safety. MRI does not depend on potentially harmful ionizing radiation, as do standard x ray and CT scans. There are no known risks specific to the procedure, other than for people who might have metal objects (e.g., surgical screws, plates, unremoved shrapnel) in their bodies.

Doctors may prescribe an MRI scan for many different areas of the body, including:

- Brain and head. MRI technology was developed because of the need for brain imaging. It is one of the few imaging tools that can see through bone (the skull) and deliver high-quality pictures of the brain's delicate soft tissue structures. MRI may be needed for patients with symptoms of a brain tumor, stroke, or brain infection such as meningitis. MRI may also be used when cognitive and/or psychological symptoms suggest brain disease (e.g., Alzheimer's disease, Huntington's disease, multiple sclerosis), or when developmental delays suggest a birth defect. MRI can also provide pictures of the sinuses and other areas of the head beneath the face. Recent refinements in MRI technology may make this form of diagnostic imaging even more useful in evaluating patients with brain cancer, stroke, schizophrenia, or epilepsy. In particular, a new 3-D approach to MRI imaging known as diffusion tensor imaging (DTI) measures the flow of water within brain tissue, allowing the radiologist to tell where normal flow of fluid is disrupted and to distinguish more clearly between cancerous and normal brain tissue. The introduction of DTI has led to a technique known as fiber tracking, which allows the neurosurgeon to tell whether a space-occupying brain tumor has damaged or displaced the nerve pathways in the white matter of the brain. This information improves the surgeon's accuracy during the actual operation.
- Spine. Spinal problems can create a host of seemingly unrelated symptoms. MRIs are particularly useful for identifying and evaluating degenerated or herniated spinal discs. They can also be used to determine the condition of nerve tissue within the spinal cord.
- Joints. MRI scanning is most commonly used to diagnose and assess joint problems. MRI can provide clear images of the bone, cartilage, ligament, and tendon that make up a joint. MRI can be used to diagnose joint injuries due to sports, advancing age, or arthritis. MRI can also detect otherwise hidden tumors or infections within a joint and can be used to diagnose developmental joint abnormalities in children.
- Skeleton. The properties of MRI that allow it to see through the skull also allow it to view the inside of bones. It can be used to detect bone cancer, inspect bone marrow for leukemia and other diseases, assess bone loss (osteoporosis), and examine complex fractures.
- The rest of the body. While CT and ultrasound satisfy most chest, abdominal, and general body imaging needs, MRI scans may be needed in certain circumstances to provide better pictures or when repeated scanning is required. The progress of some therapies, such as liver cancer therapy, needs to be monitored, and the effect of repeated x-ray exposure is a concern not encountered with MRI.

MRI is being used increasingly during operations, particularly those involving very small structures in the head and neck, as well as for preoperative assessment and planning. Intraoperative MRIs have been shown safe as well as feasible, and they improve the surgeon's ability to completely remove an entire tumor or other abnormality.

Description

In essence, MRI produces a map of hydrogen distribution in the body. Hydrogen is the simplest element known, is the most abundant element in biological tissue, and can be magnetized. It will align itself within a strong magnetic field, such as the needle of a compass. The earth's magnetic field is not strong enough to keep a person's hydrogen atoms pointing in the same direction, but the superconducting magnet of an MRI machine can. This makes up the "magnetic" part of an MRI.

Once a patient's hydrogen atoms have been aligned in the magnet, pulses of very specific radio wave frequencies are used to knock them back out of alignment. The hydrogen atoms alternately absorb and emit radio wave energy, vibrating back and forth between their resting (magnetized) state and their agitated (radio pulse) state. This is the "resonance" part of MRI.

The MRI equipment records the duration, strength, and source location of the signals emitted by the atoms as they relax and then translates the data into an image on a television monitor. The state of hydrogen in diseased tissue differs from healthy tissue of the same type, making MRI particularly

good at identifying tumors and other lesions. In some cases, chemical agents such as gadolinium can be injected to improve the contrast between healthy and diseased tissue.

A single MRI exposure produces a two-dimensional image of a slice through the entire target area. A series of these image slices composes a virtual three-dimensional view of the area.

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) is different from MRI because MRS uses a continuous band of radio wave frequencies to excite hydrogen atoms in a variety of chemical compounds other than water. These compounds absorb and emit radio energy at characteristic frequencies, or spectra, that can be used to identify them. Generally, a color image is created by assigning a color to each distinctive spectral emission. This is the "spectroscopy" part of MRS. As of 2013, diagnostic MRS was available in only a limited number of research centers.

Doctors primarily use MRS to study the brain and related disorders, such as **epilepsy**, Alzheimer's disease, brain tumors, and the effects of drugs on brain growth and metabolism. The technique is also useful in evaluating metabolic disorders of the muscles and nervous system.

Magnetic resonance angiography

Magnetic resonance angiography (MRA) is a variation on standard MRI. MRA, like other types of angiography, looks specifically at fluid flow within the blood (vascular) system, but does so without the injection of dyes or radioactive tracers. Standard MRI cannot make a good picture of flowing blood, but MRA uses specific radio pulse sequences to capture usable signals. The technique is generally used in combination with MRI to obtain images that show both vascular structure and flow within the brain and head in cases of **stroke**, or when a blood clot or aneurysm is suspected.

MRI procedure

Regardless of the exact type of MRI planned or area of the body targeted, the procedure involved is basically the same and takes place in a special MRI suite. The patient lies back on a narrow table and is made as comfortable as possible. Transmitters are positioned on the body and the cushioned table where the patient lies. The table then moves into a long tube that houses the magnet. The tube is as long as an average adult lying down, and the tube is narrow and open at both ends. Once the area to be examined has been properly positioned, a radio pulse is applied. Then, a two-dimensional image corresponding to one slice through the area is made. The table then moves a fraction of an inch and the next image is made. Each image exposure takes several seconds and the entire exam will last anywhere from 30–90 minutes. During this time, the patient is not allowed to move. If the patient moves during the scan, the picture will not be clear.

Depending on the area to be imaged, the radiowave transmitters are positioned in different locations.

- For the head and neck, a helmet similar to a hat is worn.
- For the spine, chest, and abdomen, the patient lies on the transmitters.
- For the knee, shoulder, or other joint, the transmitters are applied directly to the joint.

Additional probes monitor vital signs (e.g., pulse, respiration).

The MRI process is very noisy and confining. The patient hears a thumping sound for the duration of the procedure. Since the procedure is noisy, music supplied via earphones often is provided. Some patients become anxious or panic because they are in the small, enclosed tube. This is why vital signs are monitored. The patient and medical team also can communicate with each other. If the chest or abdomen is to be imaged, patients will be asked to hold their breath as each exposure is made. Other instructions may be given to the patient as needed. In many cases, the entire examination will be performed by an MRI operator who is not a doctor. However, the supervising radiologist should be available to consult as necessary during the exam, and will view and interpret the results some time later.

Given all its advantages, the MRI process is complex and costly. The process requires large, expensive, and complicated equipment; a highly trained operator; and a doctor specializing in **radiology**. Generally, MRI is prescribed only when serious symptoms and/or negative results from other tests indicate a need. Many times, another test is appropriate for the type of diagnosis needed.

Precautions

MRI scanning should not be used when there is the potential for an interaction between the strong MRI magnet and metal objects that might be embedded in a patient's body. The force of magnetic attraction on certain types of metal objects, including

WWW.BOOKBAZ.IR

surgical steel, could move them within the body and cause serious injury. Metal may be embedded in a person's body for several reasons:

- People with implanted cardiac pacemakers, metal aneurysm clips, or who have had broken bones repaired with metal pins, screws, rods, or plates must tell their radiologist prior to having an MRI scan. In some cases (such as a metal rod in a reconstructed leg) the difficulty may be overcome.
- Patients must tell their doctors if they have bullet fragments or other metal pieces in their body from old wounds. The suspected presence of metal, whether from an old or recent wound, should be confirmed before scanning.
- People with significant work exposure to metal particles (e.g., working with a metal grinder) should discuss this with their doctor and radiologist. The patient may need pre-scan testing—usually a single x ray of the eyes to see if any metal is present.

Chemical agents designed to improve the picture and/or allow for the imaging of blood or other fluid flow during MRA may be injected. In rare cases, patients may be allergic to or intolerant of these agents, and these patients should not receive them. If these chemical agents are to be used, patients should discuss any concerns they have with their doctor and radiologist.

The potential side effects of magnetic and electric fields on human health remain a source of debate. In particular, the possible effects on an unborn baby are not well known. Any woman who is or may be pregnant should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

As with all medical imaging techniques, **obesity** greatly interferes with the quality of MRI.

Preparation

In some cases (such as for MRI brain scanning or an MRA), a chemical designed to increase image contrast may be given by the radiologist immediately before the exam. If a patient suffers from **anxiety** or claustrophobia, drugs may be given to help the patient relax.

The patient must remove all metal objects (watches, jewelry, eyeglasses, hair clips, etc). Any magnetized objects (such as credit and bank machine cards, audio tapes, etc.) should be kept far away from the MRI equipment because they can be erased. Patients cannot bring their wallet or keys into the MRI machine. The patient may be asked to wear clothing without metal snaps, buckles, or zippers, unless a medical gown is worn during the procedure. The patient may be asked to remove any hair spray, hair gel, or cosmetics that may interfere with the scan.

Aftercare

No aftercare is necessary, unless the patient has received medication or had a reaction to a contrast agent. Normally, patients can immediately return to their daily activities. If the exam reveals a serious condition that requires more testing and/or treatment, appropriate information and counseling will be needed.

Risks

MRI poses no known health risks to the patient and produces no physical side effects. Again, the potential effects of MRI on an unborn baby are not well known. Any woman who is or may be pregnant, should carefully discuss this issue with her doctor and radiologist before undergoing a scan.

Results

A normal MRI, MRA, or MRS result is one that shows the patient's physical condition to fall within normal ranges for the target area scanned.

Abnormal results

Generally, MRI is prescribed only when serious symptoms and/or negative results from other tests indicate a need. There often exists strong evidence of a condition that the scan is designed to detect and assess. Thus, the results will often be abnormal, confirming the earlier diagnosis. At that point, further testing and appropriate medical treatment is needed. For example, if the MRI indicates the presence of a **brain tumor**, an MRS may be prescribed to determine the type of tumor so that aggressive treatment can begin immediately without the need for a surgical biopsy.

Morbidity and mortality rates

Morbidity rates are minuscule. The most common problems are minor bleeding and bruising at the site of contrast injection. Since neither are reportable events, morbidity can only be estimated. Occasionally, an unknown allergy to seafood is discovered after injecting contrast. No deaths have been reported from MRI tests.

KEY TERMS

Angiography—Any of the different methods for investigating the condition of blood vessels, usually via a combination of radiological imaging and injections of chemical tracing and contrasting agents.

Diffusion tensor imaging (DTI)—A refinement of magnetic resonance imaging that allows the doctor to measure the flow of water and track the pathways of white matter in the brain. DTI is able to detect abnormalities in the brain that do not show up on standard MRI scans.

Gadolinium—A very rare metallic element useful for its sensitivity to electromagnetic resonance, among other things. Traces of it can be injected into the body to enhance the MRI pictures.

Hydrogen—The simplest, most common element known in the universe. It is composed of a single electron (negatively charged particle) circling a nucleus consisting of a single proton (positively charged particle). It is the nuclear proton of hydrogen that makes MRI possible by reacting resonantly to radio waves while aligned in a magnetic field.

Ionizing radiation—Electromagnetic radiation that can damage living tissue by disrupting and destroying individual cells. All types of nuclear decay radiation (including x rays) are potentially ionizing. Radio waves do not damage organic tissues they pass through.

Magnetic field—The three-dimensional area surrounding a magnet, in which its force is active. During MRI, the patient's body is permeated by the force field of a superconducting magnet.

Radio waves—Electromagnetic energy of the frequency range corresponding to that used in radio communications, usually 10,000–300 billion cycles per second. Radio waves are the same as visible light, x rays, and all other types of electromagnetic radiation, but are of a higher frequency.

Alternatives

Alternatives to MRI include traditional x rays and computed axial tomography (CT) scans. An alternative to traditional closed MRI is open MRI. In open MRI, the patient is positioned beneath the magnet, but the machine remains open on all four sides. This option is becoming more common and is helpful for patients who are claustrophobic or uncomfortable with closed MRI.

Major neurocognitive disorder

Definition

Major neurocognitive disorder is a condition characterized by a progressive, irreversible decline in mental ability, accompanied by changes in behavior, personality, and in the late stage, motor functions. Major neurocognitive disorder was formerly called **dementia**, but this name was replaced in the *Diagnostic and Statistical Manual of Mental Disorders (DSM-5)* in order to reduce the stigma associated with the word *dementia*.

In major neurocognitive disorder, there is a measurable loss in more than one of the following domains: memory, attention, learning, language, perception, and social interaction. These losses must be severe enough to impair the ability of a person to perform a function such as paying bills or managing medication or to interact socially. Similar declines that do not impair daily functioning are classified as mild neurocognitive disorders. This operating definition encompasses 70–80 different types of major neurocognitive disorder. They include changes due to diseases (e.g., Alzheimer disease and Creutzfeldt-Jakob disease), changes due to **stroke** or repeated blows to the head (as suffered by boxers or football players), and damage due to long-term alcohol abuse.

Demographics

The prevalence of major neurocognitive disorder increases rapidly with age. It affects about 1% of people age 60–64 and approximately doubles every five years after age 60. By age 85, major neurocognitive disorder affects between 30% and 50% of the population in the United States, with the absolute number of individuals increasing as the population ages. The condition is somewhat more common among women than men. Some studies suggest that the risk for major neurocognitive disorder is higher among African Americans and Hispanic Americans than it is for Caucasians. More than half of all nursing home admissions occur because of major neurocognitive disorder. Surveys have found that major neurocognitive disorder is the condition most feared by older adults in the United States.

The demographic distribution of major neurocognitive disorder varies according to the cause. Moreover, reasearh in the early 2000s indicates that major neurocognitive disorder in many individuals has overlapping causes, so that it is not always easy to assess the true rates of occurrence of the different types. For example, Alzheimer disease (AD) and multi-infarct dementia (MID) are found together in about 15–20% of cases.

Alzheimer disease

AD is by far the most common cause of major neurocognitive disorder in the elderly, accounting for 60–80% of cases. It is estimated that about five million adults in the United States suffer from AD. The disease strikes women more often than men, but researchers do not know yet whether the sex ratio simply reflects the fact that women tend to live longer than men or whether female sex is itself a risk factor for AD.

Multi-infarct dementia

MID is responsible for between 15% and 20% of cases of major neurocognitive disorder (not counting cases in which it coexists with AD). Unlike AD, MID is more common in men than in women. Diabetes, high blood pressure, a history of **smoking**, and **heart disease** are all risk factors for MID. Researchers have suggested that MID is underdiagnosed and may coexist with other major neurocognitive disorders more frequently than is recognized.

Major neurocognitive disorder with Lewy bodies

Major neurocognitive disorder with Lewy bodies is thought to be the second most common form of major neurocognitive disorder after Alzheimer disease, but because researchers do not completely understand the relationship between Lewy bodies, AD, and Parkinson's disease, the demographic distribution of this type of major neurocognitive disorder is also unclear.

Other major neurocognitive disorders

Frontotemperal lobe degeneration (FLD), Pick disease, Huntington disease, Parkinson's disease, HIV infection, prion diseases, **alcoholism**, **traumatic brain injury**, and other causes of major neurocognitive disorder account for about 10% of all cases. In FLD and Pick disease, women appear to be affected slightly more often than men.

Description

The definition of major neurocognitive disorder has became more inclusive between the late twentieth century and the early 2000s. Whereas earlier descriptions of major neurocognitive disorder emphasized **memory loss**, the *DSM-5* of the American Psychiatric Association defines major neurocognitive disorder as an overall decline in intellectual function, including

difficulties with language, simple calculations, planning and judgment, social interactions, and abstract reasoning, as well as loss of memory. Major neurocognitive disorder is not caused simply by **aging**, although it is quite common in older people. Many researchers regard it as resulting from injuries, infections, brain diseases, tumors, biochemical changes within the brain, or other disorders.

One of the challenges for healthcare professionals is to differentiate the early-stage cognitive deficits of major neurocognitive disorder from normal age-related memory impairment. Individuals with age-related memory impairment may tend to learn new information more slowly, but given additional time, their cognitive performance usually is adequate. Other problems that may be mistakenly labeled major neurocognitive disorder include **delirium**, **psychosis**, depression, and the side effects of various medications

Major neurocognitive disorder can be caused by as many as 80 different diseases and conditions, ranging from dietary deficiencies and metabolic disorders to head injuries and inherited diseases. The possible causes of major neurocognitive disorder can be categorized as follows:

- Primary major neurocognitive disorder. These major neurocognitive disorders are characterized by damage to or wasting away of the brain tissue itself. They include AD, Pick disease, and FLD.
- Multi-infarct dementia (MID). Sometimes called vascular major neurocognitive disorder, this type is caused by blood clots in the small blood vessels of the brain. When the clots cut off the blood supply to the brain tissue, the brain cells are damaged and may die.
- Lewy body major neurocognitive disorder. Lewy bodies are areas of injury found on damaged nerve cells in certain parts of the brain. They are associated with AD and Parkinson's disease, but researchers do not yet know whether major neurocognitive disorder with Lewy bodies is a distinct type of major neurocognitive disorder or a variation of AD or Parkinson's disease.
- Major neurocognitive disorders related to alcoholism or exposure to heavy metals (e.g., arsenic, antimony, bismuth, mercury).
- Major neurocognitive disorder related to infectious diseases. These infections may be caused by viruses (e.g., HIV, viral encephalitis), spirochetes (e.g., Lyme disease, syphilis), or prions (e.g., Creutzfeldt-Jakob disease).
- Major neurocognitive disorder related to abnormalities in the structure of the brain. These may include a buildup of spinal fluid in the brain (hydrocephalus), tumors, or blood collecting beneath the membrane that covers the brain (subdural hematoma).

Major neurocognitive disorder may also be associated with depression, low levels of thyroid hormone, niacin, or vitamin (B_{12}) deficiency. Major neurocognitive disorder related to these conditions is often reversible.

Risk factors

Genetic factors play a role in several types of major neurocognitive disorder, but the importance of these factors in the development of the major neurocognitive disorder varies considerably. AD is known, for example, to have an autosomal (non-sex-related) dominant pattern in most early-onset cases as well as in some late-onset cases and to show different degrees of penetrance (frequency of expression) in late-life cases. Researchers have not yet discovered how the genes associated with major neurocognitive disorder interact with other risk factors to produce or trigger the major neurocognitive disorder. One non genetic risk factor being investigated is toxic substances in the environment.

Causes and symptoms

As indicated above, there are many different causes of major neurocognitive disorder. What they all have in common is damage to or degeneration of nerve cells in the brain.

Major neurocognitive disorder is marked by a gradual impoverishment of thought and other mental activities. Losses eventually affect virtually every aspect of mental functioning. The slow progression of major neurocognitive disorder is in contrast with delirium, which involves some of the same symptoms, but has a very rapid onset and fluctuating course with alteration in the level of consciousness. However, delirium may occur with major neurocognitive disorder, especially since the person with major neurocognitive disorder is more susceptible to the delirium-inducing effects of many types of drugs.

Early-onset Alzheimer disease

In early-onset AD, which accounts for 2–7% of cases of AD, the symptoms develop before age 60. Early-onset AD usually is caused by an inherited genetic mutation. Early-onset AD is also associated with **Down syndrome**, in that persons with trisomy 21 (three forms of human chromosome 21 instead of a pair) often develop early-onset AD.

WWW.BOOKBAZ.IR

Late-onset Alzheimer disease

Research indicates that late-onset Alzheimer disease is a polygenic disorder; that is, its development is influenced by more than one gene. It has been known since 1993 that a specific form of a gene for apolipoprotein E (APOE) on human chromosome 19 is a genetic risk factor for late-onset AD. In 1998, researchers at the University of Pittsburgh reported on another gene that controls the production of bleomycin hydrolase (BH) as a second genetic risk factor that acts independently of the APOE gene. In December 2000, three separate research studies reported that a gene on chromosome 10 that may affect the processing of amyloid-beta protein is also involved in the development of late-onset AD. Research in the genetic factors affecting AD is ongoing.

Multi-infarct dementia (MID)

While the chief risk factors for MID are high blood pressure, advanced age, and male sex, there is an inherited form of MID called CADASIL, which acronym for cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy. CADASIL can cause psychiatric disturbances and severe headaches as well as major neurocognitive disorder.

Several studies have documented a link between elevated levels of an amino acid called **homocysteine** in the blood and the risk of developing major neurocognitive disorder, likely vascular major neurocognitive disorder. As homocysteine concentration can be modified by diet, the finding holds the potential that one risk factor for major neurocognitive disorder may be controllable.

Frontal lobe major neurocognitive disorders

Researchers think that between 25% and 50% of cases of frontotemporal lobe degeneration involve genetic factors. Pick disease appears to have a much smaller genetic component than FLD. It is not yet known what other risk factors combine with inherited traits to influence the development of frontal lobe major neurocognitive disorders.

Familial British dementia (FBD)

FBD is a rare autosomal dominant disorder that was first reported in the 1940s in a large British family extending over nine generations. FBD resembles Alzheimer in that the individual develops a progressive major neurocognitive disorder related to amyloid deposits in the brain. In 1999, a mutated gene that produces the amyloid responsible for FBD was discovered on human chromosome 13. Studies of this mutation may yield further clues to the development of Alzheimer disease as well as FBD itself.

Creutzfeldt-Jakob disease

Although Creutzfeldt-Jakob disease is caused by a prion, researchers think that 5–15% of cases may have a genetic component.

Symptoms

The *DSM-5* distinguishes major neurocognitive disorder from mild neurocognitive disorder and specifies criteria that must be met for an individual to be diagnosed with major neurocognitive disorder. In addition the *DSM-5* emphasizes identifying the cause of the neurocognitive deficit and documenting the deficit with observations of others close to the individual and through performance on standardized neurophysical testing. The cognitive deficit must occur in at least two areas: memory, attention, learning, language, perception, and social interaction. In addition, The individual must be found to have two or more of the following deficits:

- Memory. Difficulty learning new information as well as recalling previously learned information.
- Aphasia. Aphasia refers to loss of language function. People with major neurocognitive disorder may use vague words like “it” or “thing” because they cannot recall the exact name of an object. They also may echo what other people say, or repeat a word or phrase over and over. People in the later stages of major neurocognitive disorder may totally stop speaking.
- Apraxia. Apraxia refers to loss of the ability to perform intentional movements even though the person is not paralyzed, has not lost their sense of touch, and knows what they are trying to do. For example, Individuals with apraxia may stop brushing their teeth or have trouble tying their shoelaces.
- Agnosia. Agnosia refers to loss of the ability to recognize objects even though the person’s sight and sense of touch are normal. People with severe agnosia may fail to recognize family members or their own face reflected in a mirror.
- Problems with abstract thinking and complex behavior. This criterion refers to the loss of the ability to make plans, carry out the steps of a task in the proper order, make appropriate decisions, evaluate situations, show good judgment, and so forth. For example, persons with major neurocognitive disorder might light a stove burner under a saucepan before putting food or water in the pan or be unable to record checks and balance their checkbook.

The *DSM-5* also specifies that these deficits must be severe enough to cause serious problems in the person's daily life, and these disturbances must represent a decline from a previously higher level of functioning.

Signs and symptoms are used to differentiate among the various types of major neurocognitive disorder during a diagnostic evaluation.

Alzheimer disease

Major neurocognitive disorder related to AD often progresses slowly; it may be accompanied by irritability, wide mood swings, and personality changes in the early stage. In second-stage AD, the individual typically gets lost easily, is completely disoriented with regard to time and space, and may become angry, uncooperative, or aggressive. In final-stage AD, the individual is completely bedridden, has lost control over bowel and bladder functions, and may be unable to swallow or eat. The risk of seizures increases as the individual progresses from early to end-stage AD. Death usually results from an infection or **malnutrition**.

Multi-infarct dementia

In MID, symptoms are more likely to occur after age 70. In the early stages, individuals retain their personality more fully than individuals with AD. Another distinctive feature of this type of major neurocognitive disorder is that it often progresses in a stepwise fashion; that is, individuals show rapid changes in functioning and then remain at a plateau for a while rather than showing a continuous decline. The symptoms of MID may also have a "patchy" quality; that is, some of the individual's mental functions may be severely affected while others are relatively undamaged. Other symptoms of MID include exaggerated reflexes, an abnormal gait (manner of walking), loss of bladder or bowel control, and inappropriate laughing or crying.

Major neurocognitive disorder with Lewy bodies

This type of major neurocognitive disorder may combine some features of AD, such as severe memory loss and confusion, with certain symptoms associated with Parkinson's disease, including stiff muscles, a shuffling gait, and trembling or shaking of the hands. Visual **hallucinations** may be one of the first symptoms of major neurocognitive disorder with Lewy bodies.

Frontotemporal lobe disorders

The frontotemporal lobe major disorders are gradual in onset. Pick major neurocognitive disorder is most likely to develop in persons between ages 40 and 60, whereas FLD typically begins before age 65. The first symptoms of the FLD often include socially inappropriate behavior (e.g., rude remarks, sexual acting-out, lack of personal hygiene). Individuals often are obsessed with eating and may put non food items in their mouth as well as making frequent sucking or smacking noises. In the later stages of frontal lobe major neurocognitive disorder or Pick's disease, the individual may develop muscle weakness, twitching, and **delusions** or hallucinations.

Creutzfeldt-Jakob disease

The major neurocognitive disorder associated with Creutzfeldt-Jakob disease occurs most often in persons between ages 40 and 60. It is typically preceded by a period of several weeks in which the individual complains of unusual tiredness, **anxiety**, loss of appetite, or difficulty concentrating. This type of major neurocognitive disorder also usually progresses much more rapidly than other major neurocognitive disorders, usually over a span of a few months.

In some cases, a patient's primary physician may be able to diagnose the major neurocognitive disorder; in many instances, however, the patient will be referred to a neurologist, psychiatrist, or a specialist in geriatric medicine. The differential diagnosis of major neurocognitive disorder is complicated because of the number of possible causes, because more than one cause may be present, and because major neurocognitive disorder can coexist with other conditions such as depression and delirium. Delirium is a temporary disturbance of consciousness marked by confusion, restlessness, inability to focus one's attention, hallucinations, or delusions. In elderly people, delirium is frequently a side effect of surgery, medications, infectious illnesses, or **dehydration**. Delirium can be distinguished from major neurocognitive disorder by the fact that delirium usually comes on suddenly (in a few hours or days) and may vary in severity—it is often worse at night. Major neurocognitive disorder develops much more slowly, over a period of months or years, and the patient's symptoms are relatively stable. It is possible for a person to have delirium and major neurocognitive disorder at the same time.

Another significant diagnostic distinction in elderly patients is the distinction between major neurocognitive disorder and age-associated memory impairment (AAMI). Older people with AAMI have a mild degree

KEY TERMS

Agnosia—Loss of the ability to recognize objects by use of the physical senses.

Amyloid—A waxy translucent substance composed mostly of protein that forms plaques (abnormal deposits) in the brain.

Aphasia—Loss of previously acquired ability to speak or to understand written or spoken language.

Apraxia—Impairment of the ability to make purposeful movements, but not paralysis or loss of sensation.

Creutzfeldt-Jakob disease—A degenerative disease of the central nervous system caused by a prion, or "slow virus."

Delirium—A disturbance of consciousness marked by confusion, difficulty paying attention, delusions, hallucinations, or restlessness. It can be distinguished from major neurocognitive disorder by its relatively sudden onset and variation in the severity of the symptoms.

Hematoma—An accumulation of blood, often clotted, in a body tissue or organ, usually caused by a break or tear in a blood vessel.

Huntington disease—A midlife-onset inherited disorder characterized by progressive major neurocognitive disorder and loss of control over voluntary movements. It is sometimes called Huntington's chorea.

Hydrocephalus—The excess accumulation of cerebrospinal fluid around the brain, often causing enlargement of the head.

Lewy bodies—Areas of injury found on damaged nerve cells in certain parts of the brain associated with major neurocognitive disorder.

Multi-infarct dementia—Major neurocognitive disorder caused by damage to brain tissue resulting from a series of blood clots or clogs in the blood vessels. It is also called vascular major neurocognitive disorder.

Parkinson's disease—A disease of the nervous system most common in people over 60, characterized by a shuffling gait, trembling of the fingers and hands, and muscle stiffness. It may be related in some way to Lewy body major neurocognitive disorder.

Pick's disease—A rare type of primary major neurocognitive disorder that affects the frontal lobes of the brain. It is characterized by a progressive loss of social skills, language, and memory, leading to personality changes and sometimes loss of moral judgment.

of memory loss; they do not learn new information as quickly as younger people, and they may take longer to recall a certain fact or to balance their checkbook, but they do not suffer the degree of memory impairment that characterizes major neurocognitive disorder, and they do not get progressively worse.

Patient history

The doctor will begin by taking a full history, including the patient's occupation and educational level as well as medical history. The occupational and educational history allows the examiner to make a more accurate assessment of the extent of the patient's memory loss and other evidence of intellectual decline. In some cases, the occupational history may indicate exposure to heavy metals or other toxins. A complete medical history allows the doctor to assess possibilities such as delirium, depression, alcohol-related major neurocognitive disorder, major neurocognitive disorder related to **head injury**, or major neurocognitive disorder caused by infection. It is particularly important for the doctor to have a list of all the patient's medications, including over-the-counter preparations, because of the possibility that the patient's symptoms are related to side effects.

Mental status examination

A mental status examination (MSE) evaluates the patient's ability to communicate, follow instructions, recall information, perform simple tasks involving movement and coordination, as well as his or her emotional state and general sense of space and time. The MSE includes the doctor's informal evaluation of the patient's appearance, vocal tone, facial expressions, posture, and gait as well as formal questions or instructions. A common form that has been used since 1975 is the Folstein Mini-Mental State Examination, or MMSE. Questions that are relevant to diagnosing major neurocognitive disorder include asking the patient to count backward from 100 by 7s, to make change, to name the current president, to repeat a short phrase after the examiner (e.g., "no ifs, ands, or

buts") to draw a clock face or geometric figure, and to follow a set of instructions involving movement (e.g., "Show me how to throw a ball" or "Fold this piece of paper and place it under the lamp on the bookshelf"). The examiner may test the patient's abstract reasoning ability by asking the person to explain a familiar proverb (e.g. "People who live in glass houses shouldn't throw stones") or test the patient's judgment by asking about a problem with a common-sense solution, such as what one does when a prescription runs out.

Neurological examination

A neurological examination includes an evaluation of the patient's cranial nerves and reflexes. The cranial nerves govern the ability to speak as well as sight, hearing, taste, and smell. The patient will be asked to stick out the tongue, follow the examiner's finger with the eyes, raise the eyebrows, etc. The patient is also asked to perform certain actions (e.g., touching the nose with the eyes closed) that test coordination and spatial orientation. The doctor will usually touch or tap certain areas of the body, such as the knee or the sole of the foot, to test the patient's reflexes. Failure to respond to the touch or tap may indicate damage to certain parts of the brain.

Tests

LABORATORY TESTS. Blood and urine samples are collected in order to rule out such conditions as thyroid deficiency, niacin (vitamin B_{12}) deficiency, **heavy metal poisoning**, **liver disease**, HIV infection, **syphilis**, anemia, medication reactions, or kidney failure. A **lumbar puncture** (spinal tap) may be done to rule out neurosyphilis.

DIAGNOSTIC IMAGING. The patient may be given a CT (computed tomography) scan or MRI (**magnetic resonance imaging**) to detect evidence of strokes, disintegration of the brain tissue in certain areas, **blood clots** or tumors, a buildup of spinal fluid, or bleeding into the brain tissue. PET (positron-emission tomography) or SPECT (single-emission computed tomography) imaging is not used routinely to diagnose major neurocognitive disorder but may be used to rule out Alzheimer disease or frontal lobe degeneration if a patient's CT scan or MRI is unrevealing.

Treatment

Reversible and responsive major neurocognitive disorders

Some types of major neurocognitive disorder are reversible, and a few types respond to specific treatments related to their causes. Major neurocognitive disorder related to dietary deficiencies or metabolic disorders is treated with the appropriate **vitamins** or thyroid medication. Major neurocognitive disorder related to HIV infection often responds well to zidovudine (Retrovir), a drug given to prevent the **AIDS** virus from replicating. Multi-infarct dementia is usually treated by controlling the patient's blood pressure and/or diabetes; although treatments for these disorders cannot undo damage already caused to brain tissue, they can slow the progress of the major neurocognitive disorder. Patients with alcohol-related major neurocognitive disorder often improve over the long term if they are able to stop drinking. Major neurocognitive disorders related to head injuries, **hydrocephalus**, and tumors are treated by surgery.

It is important to evaluate and treat elderly patients for depression, because the symptoms of depression in older people often mimic major neurocognitive disorder. In addition, patients who suffer from both depression and major neurocognitive disorder often show some improvement in intellectual functioning when the depression is treated.

Irreversible major neurocognitive disorders

As of 2015, there are no medications or surgical techniques that can cure Alzheimer disease, the frontal lobe major neurocognitive disorders, MID, or major neurocognitive disorder with Lewy bodies. There are also no "magic bullets" that can reverse or stop the progression of these major neurocognitive disorders.

Early intervention may allow the patient to compensate for the alterations in functioning, help to minimize complications, and have an improved quality of life. It may also allow the patient and family to plan for the future and to identify resources.

Drugs

Periodically, new drugs are studied for the treatment of major neurocognitive disorder. The only drugs approved as of 2014 for the symptomatic treatment of AD were tacrine (Cognex), donepazil (Aricept), rivastigmine (Exelon), and galantamine (Reminyl). These drugs may provide temporary improvement in cognitive functioning for about 40% of patients with mild-to-moderate AD. However, drug therapy can be complicated by forgetfulness, especially if the drug must be taken several times a day.

Psychotic symptoms, including **paranoia**, delusions, and hallucinations, may be treated with **antipsychotic drugs** such as haloperidol, chlorpromazine, risperidone, and clozapine. Side effects of these drugs can be significant. Anti-anxiety drugs such as diazepam (Valium) may improve behavioral symptoms, especially

WWW.BOOKBAZ.IR

agitation and anxiety although buspirone (BuSpar) has fewer side effects. The anticonvulsant carbamazepine (Tegretol) is also sometimes prescribed for agitation. Depression is treated with antidepressants, usually beginning with **selective serotonin reuptake inhibitors** (SSRIs) such as fluoxetine (Prozac) or paroxetine (Paxil).

In general, medications are administered cautiously in the lowest possible effective doses to individuals with major neurocognitive disorder in order to minimize side effects. Supervision of taking medications is generally required.

The primary goals of treatment for progressive major neurocognitive disorders are to preserve as much functioning and independence as possible and to maintain quality of life as long as possible. Caring for a person with major neurocognitive disorder can be difficult and complex. The patient must cope with functional and cognitive limitations, while family members or other caregivers must assume increasing responsibility for the person's physical needs. The patient and family should be educated early on in the disease progression to help them anticipate and plan for inevitable changes.

Behavioral treatment

Behavioral approaches may be used to reduce the frequency or severity of problem behaviors such as aggression or socially inappropriate conduct. Problem behavior may be a reaction to frustration or overstimulation. Understanding and modifying the situations that trigger it can be effective; strategies may include breaking down complex tasks such as dressing or feeding into simpler steps, or reducing the amount of activity in the environment to avoid confusion and agitation. Pleasurable activities such as crafts, games, and music can provide therapeutic stimulation and improve mood.

Home modification

Modifying the environment can increase safety and comfort while decreasing agitation. Home modifications for safety include removal or lock-up of hazards such as sharp knives, dangerous chemicals, and tools. Childproof latches may be used to limit access as well. Bed rails and bathroom safety rails can be important safety measures. Confusion may be reduced with the use of simpler decorative schemes and the presence of familiar objects. Covering or disguising doors may reduce the tendency to wander. Positioning the bed in view of the bathroom can decrease incontinence.

Long-term institutional care may be required for the person with major neurocognitive disorder, as profound cognitive losses often precede death by a number of years. Early planning for the financial burden of nursing **home care** is critical. Useful information about financial planning for long-term care is available through the Alzheimer's Association.

Family members or others caring for a person with major neurocognitive disorder are often subject to extreme **stress** and may develop feelings of anger, resentment, guilt, and hopelessness, in addition to the sorrow they feel for their loved one and for themselves. Depression is an extremely common consequence of being a full-time caregiver for a person with major neurocognitive disorder. Support groups can be an important way to deal with the stress of care giving. Contact numbers are available from the Alzheimer's Association; they may also be available through a local social service agency.

Alternatives

No alternative therapies have been found to conclusively prevent, reverse, or slow major neurocognitive disorders except for those caused by nutrient deficiencies. However, alternative practitioners find some of the following helpful to individual patients.

NUTRITIONAL SUPPLEMENTS. Some **nutritional supplements** may be helpful, especially if major neurocognitive disorder is caused by deficiency of these essential nutrients:

- Acetyl-L-carnitine may improve brain function and increases attention span, enhances ability to concentrate, and increases energy in individuals with Alzheimer's disease.
- Antioxidants (vitamin E, vitamin C, beta-carotene, or selenium): may reduce the risk of contracting major neurocognitive disorder by reducing the damaging effects of free radicals.
- B-complex vitamins and vitamin B_{12} may significantly improve mental function in individuals who have low levels of these essential nutrients.
- Coenzyme Q10 may help deliver more oxygen to the brain.
- DHEA may increase brain function in the elderly.
- Magnesium may be helpful if the major neurocognitive disorder is caused by magnesium deficiency and/or accumulation of aluminum in the brain.
- Phosphotidylserine deficiency may decrease mental function and cause depression.
- Zinc may boost short-term memory and increase attention span.

Herbal treatment

Herbal remedies that may be helpful in treating major neurocognitive disorder include Chinese or Korean **ginseng**, Siberian ginseng, gotu kola, and *Ginkgo biloba*. Of these, *Ginkgo biloba* is the most well known and widely accepted by Western medicine, but has not yet been proved to have a definitive positive effect on memory.

Homeopathy

A homeopathic physician may prescribe patient-specific homeopathic remedies to alleviate symptoms of major neurocognitive disorder.

Acupressure

This form of therapy uses hands to apply pressure on specific **acupressure** points to improve blood circulation and calm the nervous system.

Aromatherapy

Aromatherapists use essential oils as inhalants or in baths to improve mental performances and to calm the nerves.

Prognosis

The prognosis for reversible major neurocognitive disorder related to nutritional or thyroid problems is usually good once the cause has been identified and treated. The prognoses for major neurocognitive disorders related to alcoholism or HIV infection depend on the patient's age and the severity of the underlying disorder.

For those with irreversible progressive major neurocognitive disorder, the outlook often includes slow deterioration in mental and physical capacities ending in death. Eventually, help is often required when swallowing, walking, and even sitting become difficult. Aid can consist of preparing special **diets** that can be more easily consumed and making surroundings safe in case of falls. Lift assists in areas such as the bathroom can also be useful. On average, people with Alzheimer disease live eight years past their diagnosis, with a range from one to 20 years. Patients with frontal lobe major neurocognitive disorder or Pick disease live on average between five and 10 years after diagnosis. The course of Creutzfeldt-Jakob disease is much more rapid, with patients living between five and 12 months after diagnosis. Vascular major neurocognitive disorder is usually progressive, with death resulting from stroke, infection, or heart disease.

Prevention

Major neurocognitive disorder caused by repeated blows to the head can be prevented by avoiding sports where head **trauma** is common. Alcohol-abuse related major neurocognitive disorder can be prevented by avoiding alcohol or minimized by receiving early treatment for alcoholism. Good **nutrition** can prevent nutrient-deficiency major neurocognitive disorder. Unfortunately, most forms of major neurocognitive disorder cannot be prevented.

Malabsorption syndrome

Definition

Malabsorption syndrome is a broad term for numerous conditions that alter the ability of the intestines, primarily the small intestines, to absorb nutrients, such as fats, proteins, and carbohydrates, adequately into the bloodstream. It may refer to malabsorption of one specific nutrient or for specific fats, proteins, carbohydrates, or trace elements (micronutrients). Malabsorpotion syndrome is not a disease but a set of symptoms that is caused by some type of disorder.

Demographics

Anyone of any age, gender, or nationality can develop malabsorption syndrome.

Description

The purpose of the gastrointestinal (GI) tract, which includes the stomach and the intestines, is to digest and absorb nutrients, such as fats, proteins, and carbohydrates, water, **vitamins**, and trace **minerals**. Secretions within the GI tract break down foods ingested by humans so that eventually the final digestible products are absorbed through the intestinal cells. However, in a state involving malabsorpition syndrome, the GI track does not absorb the food nutrients as it should, which can lead to malnutrition and many of the various forms of anemia.

Causes and symptoms

Protein, fats, and carbohydrates (macronutrients) normally are absorbed in the small intestine; the small bowel also absorbs about 80% of the eight to ten liters of fluid ingested daily. Many different conditions affect fluid and nutrient absorption by the intestine. A fault in the digestive process may result from failure of the body to produce the enzymes needed to digest certain foods. Congenital structural defects or diseases of the pancreas, gall bladder, or liver may alter the digestive process. Inflammation, infection, injury, or surgical removal of portions of the intestine may also result in absorption problems; reduced length or surface area of intestine available for fluid and nutrient absorption can result in malabsorption. **Radiation therapy** may injure the mucosal lining of the intestine, resulting in **diarrhea**, which may not become evident until several years later. The use of some **antibiotics** can also affect the bacteria that normally live in the intestine and affect intestinal function.

Risk factors for malabsorption syndrome include:

- premature birth
- family history of malabsorption or cystic fibrosis
- use of certain drugs, such as mineral oil or other laxatives
- travel to foreign countries
- intestinal surgery, including bowel transplantation
- excess alcohol consumption.

The most common symptoms of malabsorption include:

- Anemia, with weakness and fatigue due to inadequate absorption of vitamin B_{12}, iron, and folic acid
- Diarrhea, steatorrhea (excessive amount of fat in the stool), and abdominal distention with cramps, bloating, and gas (flatulence) due to impaired water and carbohydrate absorption, and irritation from unabsorbed fatty acids. The individual may also report explosive diarrhea with greasy, foul-smelling stools.
- Edema (fluid retention in the body's tissues) due to decreased protein absorption
- Malnutrition and weight loss due to decreased fat, carbohydrate, and protein absorption. Weight may be 80% to 90% of usual weight despite increased oral intake of nutrients.
- Muscle cramping due to decreased vitamin D, calcium, and potassium levels
- Muscle wasting and atrophy due to decreased protein absorption and metabolism
- Perianal skin burning, itching, or soreness due to frequent loose stools.

Irregular heart rhythms may also result from inadequate levels of potassium and other electrolytes. Blood clotting disorders may occur due to a **vitamin K** deficiency. A person with malabsorption syndrome may over time lack sufficient amounts of iron, proteins, and various vitamins and minerals in the body. Consequently, malnutrition may result, along with such **anemias** involving deficiencies with vitamin K (which can cause excess bleeding), **vitamin A** (weakening of the eyes), **vitamin D** (muscle cramping), **calcium** (weakening of the bones), vitamin B_{12}, iron, and folate (**fatigue** and general weakness). Children with malabsorption syndrome often exhibit a failure to grow and thrive.

Malabsorption syndrome can be caused by poor production of enzymes used in the digestive process by the pancreas. Such problems can cause pancreatic diseases. Too much acid in the stomach or not enough bile in the liver can contribute to digestive disorders.

Several disorders can lead to malabsorption syndrome, including **cystic fibrosis**, chronic **liver disease**, chronic **pancreatitis**, Crohn's disease, **lactose intolerance**, **cholestasis**, abetalipoproteinemia, and **biliary atresia**. Other disorders can include the following.

Tropical sprue is a malabsorptive disorder that is uncommon in the United States, but seen more often in people from the Caribbean, India, or southeast Asia. Although its cause is unknown, it is thought to be related to environmental factors, including infection, intestinal parasites, or possibly the consumption of certain food toxins. Symptoms often include a sore tongue, anemia, weight loss, along with diarrhea and passage of fatty stools.

Celiac disease (also called gluten enteropathy and non-tropical sprue) is another disorder within the classification of malabsorption syndrome. In this disorder people are intolerant to food that contain gluten, or a protein contained in grains such as barley, rye, and wheat. When such foods are eaten, the body's immune system begins to fight off what it thinks are foreign materials. Consequently, the small intestines are damaged Symptoms include diarrhea, abdominal **pain**, and irritability. However, some people with Celiac disease have few symptoms, and sometimes symptoms are nonexistent.

Whipple's disease is a relatively rare malabsorptive disorder, affecting mostly middle-aged men. The cause is thought to be related to bacterial infection, resulting in nutritional deficiencies, chronic low-grade **fever**, diarrhea, joint pain, weight loss, and darkening of the skin's pigmentation. Other organs of the body may be affected, including the brain, heart, lungs, and eyes.

Short bowel syndromes—which may be present at birth (congenital) or the result of surgery—reduce the surface area of the bowel available to absorb nutrients and can also result in malabsorption syndrome. Congenital short bowel syndrome occurs in about 24 out of 100,000 live births and has a high mortality rate (about 38%).

Other conditions that can bring on malabsorption syndrome include: acquired immune deficiency syndrome (**AIDS**), some medications (such as tetracycline, **antacids**, and some that treat **obesity**), radiation treatments, and parasites.

Diagnosis

The diagnosis of malabsorption syndrome and identification of the underlying cause can require extensive diagnostic testing. The first phase involves a thorough medical history and **physical examination** by a physician, who will then determine the appropriate laboratory studies and x rays to assist in diagnosis. A 72-hour stool collection may be ordered for fecal fat measurement; increased fecal fat in the stool collected indicates malabsorption. A biopsy of the small intestine may be done to assist in differentiating between malabsorption syndrome and small bowel disease. Diagnostic sonographic (what is commonly called **ultrasound**) scans, computed tomography (CT) scans, **magnetic resonance imaging** (MRI) scans, and x ray scans, along with barium **enemas**, may also be ordered to identify abnormalities of the gastrointestinal tract and pancreas.

A newer method of obtaining diagnostic information about the small intestine was approved by the Food and Drug Administration (FDA) in 2001 and is known as capsule **endoscopy**. It includes the use of an imaging capsule, a portable belt-pack image receiver and recorder, and a specially modified computer. The patient swallows the capsule, which is the size of a large pill. A miniature lens in the capsule transmits images through an antenna/transmitter to the belt-pack receiver, which the patient wears under ordinary clothing as the person goes about daily activities. The belt-pack recording device is returned after seven or eight hours to the doctor, who then examines the images recorded as a digital video. The capsule itself is simply allowed to pass through the digestive tract.

Preparation requires only **fasting** the night before capsule endoscopy and taking nothing but clear liquids for two hours after swallowing the capsule. After four hours the patient can eat food without interfering with the test. As of the early 2010s, capsule endoscopy was used to evaluate gastrointestinal bleeding from unknown causes, inflammatory bowel disease, some malabsorption syndromes, and to monitor surgical patients following small-bowel transplantation.

Laboratory studies of the blood may include:

- Serum cholesterol. May be low due to decreased fat absorption and digestion
- Serum sodium, potassium, and chloride. May be low due to electrolyte losses with diarrhea
- Serum calcium. May be low due to vitamin D and amino acid malabsorption
- Serum protein and albumin. May be low due to protein losses
- Serum vitamin A and carotene. May be low due to bile salt deficiency and impaired fat absorption
- D-xylose test. May indicate malabsorption
- Schilling test. May indicate malabsorption of vitamin B_{12}

KEY TERMS

Anemia—A decrease in the number of red blood cells in the bloodstream, characterized by pallor, loss of energy, and generalized weakness.

Atrophy—A wasting away of a tissue or organ, often because of insufficient nutrition.

Biopsy—A tissue sample removed from the body for examination under the microscope.

Cystic fibrosis—A hereditary genetic disorder that occurs most often in Caucasians. Thick, sticky secretions from mucus-producing glands cause blockages in the pancreatic ducts and the airways.

Edema—From the Greek word meaning swelling, an excessive accumulation of fluid in the tissue spaces. Excessive generalized edema may also be referred to as ascites.

Gluten enteropathy—A hereditary malabsorption disorder caused by sensitivity to gluten, a protein found in wheat, rye, barley, and oats. Also called non tropical sprue or Celiac disease.

Intestines—The intestines, also known as the bowels, which are divided into the large and small intestines. They extend from the stomach to the anus.

Short bowel syndrome—A condition in which the bowel is not as long as normal, either because of surgery or because of a congenital defect. Because the bowel has less surface area to absorb nutrients, the condition can result in malabsorption syndrome.

Steatorrhea—An excessive amount of fat in the stool.

Trace elements—A group of elements that are present in the human body in very small amounts but are nonetheless important to good health. They include chromium, copper, cobalt, iodine, iron, selenium, and zinc. Trace elements are also called micronutrients.

Treatment

Fluid and nutrient monitoring and replacement is essential for any individual with malabsorption syndrome. Hospitalization may be required when severe fluid and electrolyte imbalances occur. Consultation with a dietitian to assist with nutritional support and meal planning is helpful. If the patient is able to eat, the diet and supplements should provide bulk and be rich in carbohydrates, proteins, fats, minerals, and vitamins. The patient should be encouraged to eat several small meals throughout the day, avoiding fluids and foods that promote diarrhea. Intake and output should be monitored, along with the number, color, and consistency of stools.

The individual with malabsorption syndrome must be monitored for **dehydration**, including dry tongue, mouth and skin; increased thirst; low, concentrated urine output; or feeling weak or dizzy when standing. Pulse and blood pressure should be monitored, observing for increased or irregular pulse rate, or **hypotension** (low blood pressure). The individual should also be alert for signs of nutrient, vitamin, and mineral depletion, including nausea or **vomiting**; fissures at corner of mouth; fatigue or weakness; dry, pluckable hair; easy bruising; tingling in fingers or toes; and numbness or burning sensation in legs or feet. Fluid volume excess, as a result of diminished protein stores, may require fluid intake restrictions. The physician should also be notified of any **shortness of breath**.

Other specific medical management for malabsorption syndrome is dependent upon the cause. Treatment for tropical sprue consists of **folic acid** supplements and long-term antibiotics. Depending on the severity of the disorder, this treatment may be continued for six months or longer. Whipple's disease also may require long-term use of antibiotics, such as tetracycline. Management of some individuals with malabsorption syndrome may require injections of vitamin B_{12} and oral iron supplements. The doctor may also prescribe enzymes to replace missing intestinal enzymes, or antispasmodics to reduce abdominal cramping and associated diarrhea. People with cystic fibrosis and chronic pancreatitis require pancreatic supplements. Those with lactose intolerance or gluten enteropathy (non tropical sprue, or Celiac disease) will have to modify their **diets** to avoid foods that they cannot properly digest.

Prognosis

The expected course for the individual with malabsorption syndrome varies depending on the cause. The onset of symptoms may be slow and difficult to diagnose. Treatment may be long, complicated, and changed often for optimal effectiveness. Patience and a positive attitude are important in controlling or curing the disorder. Careful monitoring is necessary to prevent additional illnesses caused by nutritional deficiencies. Without proper treatment for malabsorption syndrome the following conditions can result: **heart failure**, **gallstones**, **kidney stones**, anemia, **osteoporosis**, and malnutrition.

Prevention

The type of preventive measures used for malabsorption syndrome depends on the specific condition that causes it.

Malaria

Definition

Malaria is a serious **infectious disease** spread by certain mosquitoes. It is most common in tropical climates. It is characterized by recurrent symptoms of chills, **fever**, and an enlarged spleen. The disease can be treated with medication, but it often recurs. Malaria is endemic (occurs frequently in a particular locality) in many third world countries. Isolated, small outbreaks sometimes occur within the boundaries of the United States.

Malaria

Malaria caused an estimated 627,000 deaths in the world in 2012 (most recent year for which the World Health Organization [WHO] had statistics).

The majority of deaths occurred in the following regions:

- 90% in the African region
- 7% in the South-East Asia region
- 6% in the Eastern Mediterranean region
- The estimated number of deaths fell in all regions between 2000 and 2012 although there was some fluctuation year by year.
- An estimated 136 million long-lasting insecticidal nets (LLINs) were delivered to endemic countries in 2013, a major increase over the 70 million nets delivered in 2012. Population access to LLINs remains below the target of universal coverage.

Description

Malaria is quite rare in the United States. About 1,400 new cases were reported in the United States and its territories in 2000, many involving returning travelers. In addition, locally transmitted malaria has occurred in California, Florida, Texas, Michigan, New Jersey, and New York City. While malaria can be transmitted in blood, the U.S. blood supply is not screened for malaria. Widespread malarial epidemics are far less likely to occur in the United States, but small localized epidemics do occur in the Western world. As of late 2002, primary-care physicians were being advised to screen returning travelers with fever for malaria, and a team of **public health** doctors in Minnesota recommended screening immigrants, refugees, and international adoptees for the disease—particularly those from high-risk areas.

The picture is far more bleak, however, outside the territorial boundaries of the United States. One government panel warned that disaster loomed over Africa from the disease. Malaria infects between 300 and 500 million people every year in Africa, India, Southeast Asia, the Middle East, Oceania, and Central and South America. A 2002 report stated that malaria kills 2.7 million people each year, more than 75 percent of them African children under the age of five. It was predicted that within five years, malaria would kill about as many people as does **AIDS**. As many as half a billion

people worldwide are left with chronic anemia due to malaria infection. In some parts of Africa, people battle up to 40 or more separate episodes of malaria in their lifetime. The spread of malaria is becoming even more serious as the parasites that cause malaria develop resistance to the drugs used to treat the condition. In

late 2002, a group of public health researchers in Thailand reported that a combination treatment regimen involving two drugs, dihydroartemisinin and azithromycin, showed promise in treating multidrug-resistant malaria in southeast Asia.

Causes and symptoms

Human malaria is caused by four different species of a parasite belonging to genus *Plasmodium*: *Plasmodium falciparum* (the most deadly), *Plasmodium vivax*,-*Plasmodium malariae*, and *Plasmodium ovale*. The last two are fairly uncommon. Many animals can get malaria, but human malaria does not spread to animals, nor does animal malaria spread to humans.

A person gets malaria when bitten by a female mosquito that is looking for a blood meal and is infected with the malaria parasite. The parasites enter the blood stream and travel to the liver, where they multiply. When they reemerge into the blood, symptoms appear. By the time a patient shows symptoms, the parasites have reproduced very rapidly, clogging blood vessels and rupturing blood cells.

Malaria cannot be casually transmitted directly from one person to another. Instead, a mosquito bites an infected person and then passes the infection on to the next human it bites. It is also possible to spread malaria via contaminated needles or in blood transfusions. This is why all blood donors are carefully screened with questionnaires for possible exposure to malaria.

It is possible to contract malaria in non endemic areas, although such cases are rare. Nevertheless, at least 89 cases of so-called airport malaria, in which travelers contract malaria while passing through crowded airport terminals, have been identified between 1969 and 2002.

The amount of time between the mosquito bite and the appearance of symptoms varies, depending on the strain of parasite involved. The incubation period is usually between 8 and 12 days for falciparum malaria, but it can be as long as a month for the other types. Symptoms from some strains of *P.vivax* may not appear until 8–10 months after the mosquito bite occurred.

The primary symptom of all types of malaria is the "malaria ague" (chills and fever). In most cases, the fever has three stages, beginning with uncontrollable shivering for an hour or two, followed by a rapid spike in temperature (as high as 106°F), which lasts three to six hours. Then, just as suddenly, the patient begins to sweat profusely, which will quickly bring down the fever. Other symptoms may include **fatigue**, severe **headache**, or **nausea and vomiting**. As the sweating subsides, the patient typically feels exhausted and falls asleep. In many cases, this cycle of chills, fever, and sweating occurs every other day, or every third day, and may last for between a week and a month. Those with the chronic form of malaria may have a relapse as long as 50 years after the initial infection.

Falciparum malaria is far more severe than other types of malaria because the parasite attacks all red blood cells, not just the young or old cells, as do other types. It causes the red blood cells to become very "sticky." A patient with this type of malaria can die within hours of the first symptoms. The fever is prolonged. So many red blood cells are destroyed that they block the blood vessels in vital organs (especially the kidneys), and the spleen becomes enlarged. There may be brain damage, leading to **coma** and convulsions. The kidneys and liver may fail.

Malaria in **pregnancy** can lead to premature delivery, **miscarriage**, or **stillbirth**.

Certain kinds of mosquitoes (called anopheles) can pick up the parasite by biting an infected human. (The more common kinds of mosquitoes in the United States do not transmit the infection.) This is true for as long as these humans have parasites in their blood. Since strains of malaria do not protect against each other, it is possible to be reinfected with the parasites again and again. It is also possible to develop a chronic infection without developing an effective immune response.

Diagnosis

Malaria is diagnosed by examining blood under a microscope. The parasite can be seen in the blood smears on a slide. These blood smears may need to be repeated over a 72-hour period in order to make a diagnosis. Antibody tests are not usually helpful because many people developed antibodies from past infections, and the tests may not be readily available. A new laser test to detect the presence of malaria parasites in the blood was developed in 2002, but is still under clinical study.

Two new techniques to speed the laboratory diagnosis of malaria show promise. The first is acridine orange (AO), a staining agent that works much faster (3–10 min.) than the traditional Giemsa stain (45–60 min.) in making the malaria parasites visible under a microscope. The second is a bioassay technique that measures the amount of a substance called histadine-rich protein II (HRP2) in the patient's

WWW.BOOKBAZ.IR

blood. It allows for a very accurate estimation of parasite development. A dip strip that tests for the presence of HRP2 in blood samples appears to be more accurate in diagnosing malaria than standard microscopic analysis.

Individuals who become ill with chills and fever after being in an area where malaria exists must see a doctor and mention their recent travel to endemic areas. A person with the above symptoms who has been in a high-risk area should insist on a blood test for malaria. The doctor may believe the symptoms are just the common flu virus. Malaria is often misdiagnosed by North American doctors who are not used to seeing the disease. Delaying treatment of falciparum malaria can be fatal.

Treatment

Falciparum malaria is a medical emergency that must be treated in the hospital. The type of drugs, the method of giving them, and the length of the treatment depend on where the malaria was contracted and how sick the patient is.

For all strains except falciparum, the treatment for malaria is usually chloroquine (Aralen) by mouth for three days. Those falciparum strains suspected to be resistant to chloroquine are usually treated with a combination of quinine and tetracycline. In countries where quinine resistance is developing, other treatments may include clindamycin (Cleocin), mefloquin (Lariam), or sulfadoxone/pyrimethamine (Fansidar). Most patients receive an antibiotic for seven days. Those who are very ill may need intensive care and intravenous (IV) malaria treatment for the first three days.

Anyone who acquired falciparum malaria in the Dominican Republic, Haiti, Central America west of the Panama Canal, the Middle East, or Egypt can still be cured with chloroquine. Almost all strains of falciparum malaria in Africa, South Africa, India, and southeast Asia are now resistant to chloroquine. In Thailand and Cambodia, there are strains of falciparum malaria that have some resistance to almost all known drugs.

A patient with falciparum malaria needs to be hospitalized and given **antimalarial drugs** in different combinations and doses depending on the resistance of the strain. The patient may need IV fluids, red blood cell transfusions, **kidney dialysis**, and assistance breathing.

A drug called primaquine may prevent relapses after recovery from *P. vivax* or *P. ovale*. These relapses are caused by a form of the parasite that remains in the liver and can reactivate months or years later.

Another drug, halofantrine, is available abroad. While it is licensed in the United States, it is not marketed in the States, and it is not recommended by the Centers for Disease Control and Prevention in Atlanta.

Alternatives

The Chinese herb qiinghaosu (the Western name is artemisinin) has been used in China and Southeast Asia to fight severe malaria, and became available in Europe in 1994. Because this treatment often fails, it is usually combined with another antimalarial drug (mefloquine) to boost its effectiveness. It is not available in the United States and other parts of the developed world due to fears of its toxicity, in addition to licensing and other issues.

A Western herb called wormwood (*Artemesia annua*) that is taken as a daily dose can be effective against malaria. Protecting the liver with herbs like goldenseal (*Hydrastis canadensis*), Chinese goldenthread (*Coptis chinensis*), and milk thistle (*Silybum marianum*) can be used as preventive treatment. Not getting mosquito bites while individuals are in the tropics is another possible way to avoid malaria.

Researchers are studying a traditional African herbal remedies against malaria. Extracts from *Microglossa pyrifolia*, for example, a trailing shrub belonging to the daisy family (Asteraceae), show promise in treating drug-resistent strains of *P. falciparum*.

Prognosis

If treated in the early stages, malaria can be cured. Those who live in areas where malaria is epidemic, however, can contract the disease repeatedly, never fully recovering between bouts of acute infection.

Prevention

Research continues on a malarial vaccine, but the complex life cycle of the malaria parasite makes it difficult. A parasite has much more genetic material than a virus or bacterium. For this reason, a successful vaccine has not yet been developed.

Malaria is an especially difficult disease to prevent by **vaccination** because the parasite goes through several separate stages. One promising vaccine appears to have protected up to 60% of people exposed to malaria. This was evident during field trials for the

KEY TERMS

Arteminisinins—A family of antimalarial products derived from an ancient Chinese herbal remedy. Two of the most popular varieties are artemether and artesunate, used mainly in southeast Asia in combination with mefloquine.

Chloroquine—An antimalarial drug that was first used in the 1940s, until the first evidence of quinine resistance appeared in the 1960s. It is now ineffective against falciparum malaria almost everywhere. However, because it is inexpensive, it is still the antimalarial drug most widely used in Africa. Native individuals with partial immunity may have better results with chloroquine than a traveler with no previous exposure.

Mefloquine—An antimalarial drug that was developed by the United States Army in the early 1980s. Today, malaria resistance to this drug has become a problem in some parts of Asia (especially Thailand and Cambodia).

Quinine—One of the first treatments for malaria, a natural product made from the bark of the Cinchona tree. It was popular until being superseded by chloroquine in the 1940s. In the wake of widespread chloroquine resistance, however, it has become popular again. Quinine, or its close relative quinidine, can be given intravenously to treat severe *Falciparum* malaria.

Sulfadoxone/pyrimethamine (Fansidar)—An antimalarial drug developed in the 1960s. It is the first drug tried in some parts of the world where chloroquine resistance is widespread. It has been associated with severe allergic reactions due to its sulfa component.

drug that were conducted in South America and Africa. It was not yet commercially available.

The World Health Association (WHO) has been trying to eliminate malaria for the past 30 years by controlling mosquitoes. Their efforts were successful as long as the pesticide DDT killed mosquitoes and antimalarial drugs cured those who were infected. Today, however, the problem has returned a hundredfold, especially in Africa. Because both the mosquito and parasite are now extremely resistant to the insecticides designed to kill them, governments are trying to teach people to take antimalarial drugs as a preventive medicine and avoid getting bitten by mosquitoes.

One strategy involved the development of genetically modified non-biting mosquitoes. A research team in Italy studied the feasibility of this means of controlling malaria.

Travelers to high-risk areas should use insect repellant containing DEET for exposed skin. Because DEET is toxic in large amounts, children should not use a concentration higher than 35%. DEET should not be inhaled. It should not be rubbed onto the eye area, on any broken or irritated skin, or on children's hands. It should be thoroughly washed off after users come indoors.

Those who use the following preventive measures get fewer infections than those who do not:

- Between dusk and dawn, remain indoors in well-screened areas.
- Sleep inside pyrethrin or permethrin repellent-soaked mosquito nets.
- Wear clothes over the entire body.

People visiting endemic areas should take antimalarial drugs starting a day or two before they leave the United States. The drugs used are usually chloroquine or mefloquine. This treatment is continued through at least four weeks after leaving the endemic area. However, even those who take antimalarial drugs and are careful to avoid mosquito bites can still contract malaria.

International travelers are at risk for becoming infected. Many Americans who have acquired falciparum malaria were visiting sub-Saharan Africa; travelers in Asia and South America are less at risk. Travelers who stay in air conditioned hotels on tourist itineraries in urban or resort areas are at lower risk than backpackers, missionaries, and Peace Corps volunteers. Some people in western cities where malaria does not usually exist may acquire the infection from a mosquito carried onto a jet. This is called airport or runway malaria.

Malignant hyperthermia

Definition

Malignant hyperthermia (MH) is a condition that causes a number of physical changes to occur among genetically susceptible individuals when they are exposed to a particular muscle relaxant or certain types of medications used for **anesthesia**. The changes may include increased rate of breathing, increased heart rate, muscle stiffness, and significantly increased body temperature (i.e., hyperthermia). Although MH can usually be treated successfully, it sometimes leads to long-term physical illness or death. Research has identified a number of genetic regions that may be linked to an increased MH susceptibility.

KEY TERMS

Anesthesia—Lack of normal sensation (especially to pain) brought on by medications just prior to surgery or other medical procedures.

Genetic heterogeneity—The occurrence of the same or similar disease, caused by different genes among different families.

Hyperthermia—Body temperature that is much higher than normal (i.e. higher than 98.6°F).

Masseter spasm—Stiffening of the jaw muscles. Often one of the first symptoms of malignant hyperthermia susceptibility that occurs after exposure to a trigger drug.

Metabolism—The total combination of all of the chemical processes that occur within cells and tissues of a living body.

Sarcoplasmic reticulum—A system of tiny tubes located inside muscle cells that allow muscles to contract and relax by alternatively releasing and storing calcium.

Trigger drugs—Specific drugs used for muscle relaxation and anesthesia that can trigger an episode of malignant hyperthermia in a susceptible person. The trigger drugs include halothane, enflurane, isoflurane, sevoflurane, desflurane, methoxyflurane, ether, and succinylcholine.

Description

Unusual response to anesthesia was first reported in a medical journal during the early 1960s, when physicians described a young man in need of urgent surgery for a serious injury. He was very nervous about exposure to anesthesia, since he had 10 close relatives who died during or just after surgeries that required anesthesia. The patient himself became very ill and developed a high temperature after he was given anesthesia. During the next decade, more cases of similar reactions to anesthesia were reported, and specialists began using the term *malignant hyperthermia* to describe the newly recognized condition. The word *hyperthermia* was used because people with this condition often quickly develop a very high body temperature. The word *malignant* referred to the fact that the majority (70–80%) of affected individuals died. The high death rate in the 1960s occurred because

the underlying cause of the condition was not understood, nor was there any known treatment (other than basically trying to cool the person's body with ice).

Increased awareness of malignant hyperthermia and scientific research during the following decades improved medical professionals' knowledge about what causes the condition, how it affects people, and how it should be treated. MH can be thought of as a chain reaction that is triggered when a person with MH susceptibility is exposed to specific drugs commonly used for anesthesia and muscle relaxation.

Triggering drugs that may lead to malignant hyperthermia include:

- halothane
- enflurane
- isoflurane
- sevoflurane
- desflurane
- methoxyflurane
- ether
- succinylcholine

Once MH susceptible persons are exposed to one or more of these anesthesia drugs, they can develop a variety of signs. One of the first clues occurs when they are given a muscle relaxant called succinyl choline. This drug generally causes some stiffness in the masseter (jaw) muscles in most people. However, individuals with MH susceptibility can develop a much more severe form of jaw stiffness called *masseter spasm* when they receive this drug. They may develop muscle stiffness in other parts of their bodies as well. When exposed to any of the trigger drugs (inhalants for anesthesia), people with MH susceptibility can develop an increased rate of metabolism in the cells of their body, resulting in rapid breathing, rapid heartbeat, high body temperature (over 110°F/43°C), muscle stiffness, and muscle breakdown. If these signs are not recognized, treated, or able to be controlled, brain damage or death can occur due to internal bleeding, **heart failure**, or failure of other organs.

The series of events that occur after exposure to trigger drugs is activated by an abnormally high amount of **calcium** inside muscle cells. This is due to changes in the chemical reactions that control muscle contraction and the production of energy. Calcium is normally stored in an area called the sarcoplasmic reticulum, which is a system of tiny tubes located inside muscle cells. This system of tubes allows muscles to contract (by releasing calcium) and to relax (by storing calcium) in muscle cells. Calcium also plays an important role in the production of energy inside cells (i.e. metabolism). There are at least three important proteins located in (or nearby) the sarcoplasmic reticulum that control how much calcium is released into muscle cells and thus help muscles contract. One of these proteins is a calcium release channel protein that has been named the *ryanodine receptor protein*, or RYR. This protein (as well as the gene that tells the body how to make it) has been an important area of research. For some reason, when people with MH susceptibility are exposed to a trigger drug, they can develop very high levels of calcium in their muscle cells. The trigger drugs presumably stimulate the proteins that control the release of calcium, causing them to create very high levels of calcium in muscle cells. This abnormally high calcium level then leads to increased metabolism, muscle stiffness, and the other symptoms of MH.

The amount of time that passes between the exposure to trigger drugs and the appearance of the first symptoms of MH varies among people. Symptoms begin within 10 minutes for some individuals, although several hours may pass before symptoms appear in others. This means that some people do not show signs of MH until they have left the operating room and are recovering from surgery. In addition, some individuals who inherit MH susceptibility may be exposed to trigger drugs numerous times during multiple surgeries without any complications. However, they still have an increased risk to develop an MH episode during future exposures. This means that people who have an increased risk for MH susceptibility due to their family history cannot presume they are not at risk simply because they previously had successful surgeries. Although MH was frequently a fatal condition in the past, the drug dantrolene **sodium** became available in 1979, which greatly decreased the rate of both death and disability.

Demographics

The exact number of individuals who are born with a genetic change that causes MH susceptibility is not known. It is estimated that internationally one in 50,000 people who are exposed to anesthesia develop an MH reaction. Among children, it is estimated that one in 5,000 to one in 15,000 develop MH symptoms when exposed to anesthesia. MH has been seen in many countries, although there are some geographic areas where it occurs more often in the local populations, including parts of Wisconsin, North Carolina, Austria, and Quebec.

WWW.BOOKBAZ.IR

Causes and symptoms

Susceptibility to MH is generally considered to be inherited as an autosomal dominant trait. *Autosomal* means that males and females are equally likely to be affected. *Dominant* refers to a specific type of inheritancein which only one copy of a person's gene pair needs to be changed in order for the susceptibility to be present. In this situation, an individual susceptible to MH receives a changed copy of the same gene from one parent (who is also susceptible to MH). This means that a person with MH susceptibility has one copy of the changed gene and one copy of the gene that works well. The chance that a parent with MH susceptibility will have a child who is also susceptible is 50% for each **pregnancy**. The same parent would also have a 50% chance to have a non susceptible child with each pregnancy.

It is not unusual for people to not know they inherited a genetic change that causes MH susceptibility. Typically individuals do not show symptoms unless they are exposed to a specific muscle relaxant or certain anesthetics, which may not be needed by every person during the person's lifetime. In addition, people who inherit MH susceptibility do not always develop a reaction to trigger drugs, which means their susceptibility may not be recognized even if they do have one or more surgeries. Once MH susceptibility is diagnosed in an individual, however, it is important for that person's family members to know they too have a risk for MH susceptibility, since it is a dominant condition. This means that anyone with a family member who has MH susceptibility should tell their doctor about their family history. Since MH may go unrecognized, it is important that anyone who has had a close relative die from anesthesia notify the anesthesiologist before any type of surgery is planned. People with a family history of MH susceptibility may choose to meet with a genetic counselor to discuss the significance of their family history as well. In addition, relatives of an affected person may consider having a test to see if they also inherited MH susceptibility.

Although there are many people who have the same symptoms of MH when exposed to trigger drugs, genetic research has shown that there are probably many genes, located on different chromosomes, that can all lead to MH susceptibility. This indicates that there is genetic heterogeneity among different families with MH susceptibility, meaning that different genes can lead to the same or similar disease among different families. Researchers identified six different types of MH susceptibility. Although specific genes have been discovered for some of these types, others have been linked only to specific chromosomal regions.

There are many different types of genetic changes in the gene that can all lead to MH susceptibility, and many families have changes that are unique. As a result, genetic testingof the RYR1 gene is complicated, time consuming, and often cannot locate all possible genetic changes. In addition, genetic testing for families may become more complex as knowledge about MH grows. Although MH susceptibility has typically been described as an autosomal dominant trait caused by a single gene that is passed from one generation to the next, MH susceptibility may actually depend upon various genetic changes that occur in more than one gene. Further research may clarify this issue.

Although the specific symptoms of malignant hyperthermia can vary, the most common findings include:

- stiffness/spasms of jaw muscles and other muscles
- rapid breathing, causing decreased oxygen and increased carbon dioxide in the blood
- rapid or irregular heartbeat
- high body temperature (over 110°F)
- muscle breakdown (may cause dark or cola-colored urine)
- internal bleeding, kidney failure, brain damage, or death (if not treated successfully)

Diagnosis

The diagnosis of MH susceptibility can be made before or during a reaction to a triggering drug. Ideally, the diagnosis is made before a susceptible individual is exposed and/or develops a reaction. This is possible for people who learn they have an increased chance for MH because they have a relative with MH susceptibility. Testing these individuals requires a surgical procedure called a muscle biopsy, in which a piece of muscle tissue is removed from the body (usually from the thigh). Safe (i.e., non-triggering) anesthetics are used during the procedure. The tissue sample is taken to a laboratory and is exposed to halothane (a triggering anesthetic) and **caffeine**, both of which cause any muscle tissue to contract, or tighten. Thus, the test is called the caffeine halothane contracture test (CHCT). Muscle tissue taken from individuals with MH susceptibility is more sensitive to caffeine and halothane, causing it to contract more strongly than normal muscle tissue from non-susceptible people. This type of test is a very accurate way to predict whether a person has MH susceptibility or not. However, the test does require surgery, time to recover (typically three days), and it is expensive (approximately US$2,500). In the United States, many insurance companies will pay for the testing if it is needed. Although the test is not

available in every state or country, there are at least 40 medical centers worldwide that can perform the test.

Unfortunately, not all MH susceptible people will learn from their family histories that they have an increased risk for MH before they are exposed to a trigger drug. For these individuals, the diagnosis of MH susceptibility is often made during surgery by the anesthesiologist (a physician specializing in anesthesia) who is providing the anesthesia medications. Other healthcare specialists also may notice symptoms of MH during or after surgery. Symptoms such as rapid breathing, rapid heart rate, and high body temperature can usually be detected with various machines or devices that examine basic body functions during surgery. Muscle stiffness of the jaw, arms, legs, stomach, and chest may be noticed as well. These symptoms may happen during surgery or even several hours later. If the diagnosis is made during or after surgery, immediate treatment is needed to prevent damage to various parts of the body or death. If a person has a suspicious reaction to anesthesia, he or she may undergo a muscle biopsy to confirm MH susceptibility at a later date. Until genetic technology improves, the contracture test that is done on muscle tissue will likely remain the "gold standard" for diagnosis of MH susceptibility.

Treatment

The early identification of an MH episode allows for immediate treatment with an antidote called dantrolene sodium. This medication prevents the release of calcium from the sarcoplasmic reticulum, which decreases muscle stiffness and energy production in the cells. If hyperthermia develops, the person's body can be cooled with ice. In addition, the anesthesiologist will change the anesthetic from a trigger drug to a non trigger drug. Immediate treatment is necessary to prevent serious illness and/or death.

Once a person with definite or suspected MH susceptibility is diagnosed (by an MH episode, muscle biopsy, or family history), prevention of an MH episode is possible. There are many types of non triggering anesthetic drugs and **muscle relaxants** that can be used during surgical procedures. The important first step in this process is for people with known or suspected MH susceptibility to talk with their doctors before any surgery, so that only non-triggering drugs are used. People with definite or suspected MH susceptibility should always carry some form of medical identification that describes their diagnosis in case emergency surgery is needed. The Malignant Hyperthermia Association of the United States provides wallet-sized emergency medical ID cards for its members.

Prognosis

Early diagnosis and treatment of MH episodes with dantrolene sodium has dramatically improved the prognosis for people who develop MH during or just after surgery. When the condition was first recognized in the 1960s, no real treatment (other than cooling the person's body) was available, and only 20–30% of people who developed MH survived. When the antidote (dantrolene sodium) became available in 1979, the survival rate increased to 70–80%. However, 5–10% of people who develop MH after exposure to a trigger drug still may die even with proper medication and care. Among those who do survive, some are disabled due to kidney, muscle or brain damage. The best prognosis exists for people with definite or suspected MH susceptibility who are able to prevent exposures to trigger drugs by discussing their history with their doctors.

Prevention

Improved genetic testing in the future may help identify most or all people with inherited MH susceptibility, so they too may prevent exposures that trigger MH episodes.

Malingering

Definition

In the context of medicine, malingering is the act of intentionally feigning or exaggerating physical or psychological symptoms for motives involving personal or financial gain. Examples of malingering include fabricating mental or physical disorders in order to avoid school, work, or military service; or to obtain financial compensation, avoid criminal prosecution, or obtain **narcotics** and other drugs.

Demographics

Malingering can occur in any individual all over the world. Because it is often impossible to determine who is malingering and who is not, it is very difficult to statistically measure how frequently malingering occurs.

Description

People may feign physical or psychological illness for any number of reasons. Faked illness can get them out of work, military duty, or criminal prosecution. It can also help them obtain financial compensation through insurance claims, lawsuits, or workers' compensation. Feigned symptoms may also be a way of getting the doctor to prescribe certain drugs.

According to the American Psychiatric Association, patients who malinger are different from people who invent symptoms for sympathy (factitious diseases). Patients who malinger clearly have something tangible to gain. People with factitious diseases appear to have a need to play the "sick" role. They may feign illness for attention or sympathy.

Malingering may take the form of complaints of chronic **whiplash pain** from automobile accidents. Whiplash claims are controversial. Although some people clearly do suffer from whiplash injury, others may be exaggerating the pain for insurance claims or lawsuits. Some intriguing scientific studies have shown that chronic whiplash pain after automobile accidents is almost nonexistent in countries where the legal systems do not encourage personal injury lawsuits or financial settlements. The psychological symptoms experienced by survivors of disaster (**post-traumatic stress disorder**) are also faked by malingerers.

Causes and symptoms

People malinger for personal gain. The symptoms may vary, but generally are similar to symptoms involving **chronic fatigue syndrome** or chronic pain. Generally, malingerers complain of psychological disorders such as **anxiety**. They may also complain of chronic pain for which objective tests such as x rays cannot find any physical cause.

Many dishonest methods are used by individuals feigning symptoms of malingering. Some of these include harming oneself, trying to convince medical professionals of the presence of disease after learning about its details (such as symptoms) in medical textbooks, taking drugs that provoke certain symptoms common in some diseases, performing excess **exercise** to induce muscle strain or other physical types of ailments, and overdosing on drugs.

Diagnosis

Malingering may be suspected in the following situations:

- when a patient is referred for examination by an attorney
- when the onset of illness coincides with a large financial incentive, such as a new disability policy
- when objective medical tests do not confirm the patient's complaints
- when the patient does not cooperate with the diagnostic work-up or prescribed treatment
- when the patient has antisocial attitudes and behaviors (antisocial personality)

The diagnosis of malingering is a challenge for doctors. On the one hand, the doctor does not want to overlook a treatable disease. On the other hand, he or she does not want to continue ordering tests and treatments if the symptoms are faked. Malingering is difficult to distinguish from certain legitimate **personality disorders**, such as factitious diseases or post-traumatic distress syndrome. In legal cases, malingering patients may be referred to a psychiatrist. Psychiatrists use certain written tests to try to determine whether the patient is faking the symptoms.

KEY TERMS

Antisocial personality—A personality characterized by attitudes and behaviors at odds with society's customs and moral standards, including illegal acts.

Factitious diseases—Conditions in which symptoms are deliberately manufactured by patients in order to gain attention and sympathy. Patients with factitious diseases do not fake symptoms for obvious financial gain or to evade the legal system.

Post-traumatic stress disorder (PTSD)—A disorder that occurs among survivors of severe environmental stress such as a tornado, an airplane crash, or military combat. Symptoms include anxiety, insomnia, flashbacks, and nightmares. Patients with PTSD are unnecessarily vigilant; they may experience survivor guilt, and they sometimes cannot concentrate or experience joy.

Treatment

In a sense, malingering cannot be treated because the American Psychiatric Association does not recognize it as a personality disorder. Patients who are purposefully faking symptoms for gain do not want to be cured. Often, the malingering patient fails to report any improvement with treatment, and the doctor may try many treatments without success. Treatment may include cognitive behavioral therapy, **psychotherapy**, **family therapy**, or other such types of psychological treatments. However, treatment sessions may be difficult because the malingerer may not accept such treatment when confronted with it. The malingerer may then go to another medical facility where their symptoms and medical history are not known, and they are free to once again pursue their acts of malingering.

Prognosis

If malingerers accept their malady, then treatment can be positively received, and malingering minimized or even eliminated. However, if they do not accept their own predicament, then treatment is often difficult and lengthy, with the outcome often times coming out without a resolution. Treatment of malingers by the medical profession has found that most patients do not accept psychiatric help. In addition, the recovery of malingers, who do not accept and acknowledge their problem, is rarely accomplished.

Prevention

The ability to accurately prevent people from malingering is difficult at best. When not detected and allowed to persist in society, the act of malingerers placed enormous financial burdens on any country's healthcare system. According to the Texas Department of Insurance, fraud that includes malingering costs the U.S. insurance industry approximately $150 billion each year.

Mallet finger

Definition

Mallet finger refers to the involuntary flexion (bending) of the distal phalanx of a finger caused by the disruption or tearing of its extensor digitorum tendon at the distal interphalangeal joint (DIPJ). That is, a deformity has occurred in the finger when a tendon within that finger is damaged (lacerated) by a blunt impact. The result is that instead of being in a resting position, the outermost joint on the back of the finger remains abnormally flexed. Because of this description, it is also called extensor tendon injury. Mallet finger is also called dropped finger.

WWW.BOOKBAZ.IR

Description

Tendons are the strong "cables" between muscles and bones that help control movements of the body. They consist of white, glistening, fibrous cords of various length and thickness, either round or flattened, and lacking in elasticity. In mallet finger, which often occurs as a sports-related injury, the tendon on the back of the finger becomes damaged or torn near the outermost joint. Without the support provided by the tendon, the short bone at the tip of the finger drops downward at an awkward angle. This bone, referred to as the "distal phalanx" of a finger, is the one furthest from the palm. In addition to tendon damage, mallet finger may involve a fracture of the distal phalanx.

Because the injury often occurs in such sports as baseball and softball (along with basketball and volleyball), it is commonly called baseball finger. The injury occurs when a ball (or some other object such as a knife) strikes the tip of the finger on the outstretched hand, jams the finger, and damages the tendon within the finger so it can no longer straighten the finger. This contact causes rupturing (hyperflexion) of the extensor digitorum tendon. In some incidences, the force of the ball or object causes a part of the bone along the tendon to pull away.

Demographics

Anyone who attempts to catch a ball (such as a football) or contacts an object (such as hitting the finger against a hard, stationary table or cabinet) has the potential of getting mallet finger. Spraining the interphalangeal joint is common in sports. The most common injury of the interphalangeal joints is a sprain of the proximal interphalangeal joint (PIPJ). This injury is often called a jammed finger. Mallet finger occurs less frequently than a jammed finger.

Causes and symptoms

Mallet finger usually occurs while individuals are playing a sport that involves a ball—for example, reaching out to catch a hard pass in basketball or barehanding a baseball. Instead of landing on the palm of the hand, the ball accidentally hits the tip of an extended (or partially extended) finger. This straight-on impact causes instantaneous stretch of the tendon, which may overextend or tear away. Mallet finger can also result from hitting the hand against a hard object or receiving a cut from a sharp edge such as a knife.

Symptoms of mallet finger include **pain** and swelling around the top part of the finger, near the outermost joint. These symptoms occur immediately after the injury. Redness, bruising, and further swelling develop soon afterward. The finger may be unable to be extended; however, it still may be moved with help. Sometimes blood collects beneath the nail of the affected finger. If the object also strikes the nail, it may become detached. The tip of the finger has an abnormal-looking downward droop.

Diagnosis

Mallet finger is usually diagnosed after a relatively brief **physical examination** conducted by an emergency care physician or by an orthopedist, the type of doctor who specializes in such injuries. The downward droop of the fingertip is the major indication of mallet finger, along with the tenderness and pain that occurs in the affected area. X rays will be taken to determine if the bone at the top of the finger has been fractured. Mallet finger is typically covered by medical insurance.

Treatment

If symptoms of mallet finger appear, the affected individual should consult a physician or seek emergency care. In the meantime, ice (wrapped in a towel or cloth) can be applied to the affected area to help reduce swelling and tenderness, and to alleviate pain.

Treatment usually involves first applying ice to the finger, with the affected hand elevated above the heart. The medical professional will in almost all cases attach a splint, sometimes called a mallet splint, around the top of the affected finger in order to keep it extended and allow the injury to heal. The splint must be worn at all times for six to eight weeks, though it may be briefly removed to wash the finger, but with extreme care so as not to allow the fingertip to bend. For the next six to eight weeks after that, the splint need only be worn during sleep or athletic activities.

Two other treatment wearing of a small plaster cast or wearing an extension block k-wire for approximately four weeks. In all cases, the device helps to immobilize the finger so that the tendon can reattach itself.

After the full amount of time has expired for wearing the device, it is then usually worn less often, but for another three to four weeks.

If the bone at the top of the finger has sustained a large fracture, surgery may be necessary. An orthopedic surgeon or a hand specialist will usually perform the surgery. If the tendon was damaged due to a cut, stitches may be required both to repair the tendon and

KEY TERMS

Distal phalanx—The outermost bone of any finger or toe.

Fracture—A break in bone.

Orthopedist—A doctor who specializes in disorders of the musculoskeletal system.

Phalanx—Any of the digital bones of the hand or foot. Humans have three phalanges to each finger and toe with the exception of the thumb and big toe which have only two each.

Tendon—A tough cord of dense white fibrous connective tissue that connects a muscle with some other part, especially a bone, and transmits the force which the muscle exerts.

to adequately close the wound. In addition, if blood is present underneath the nail, or if the nail is detached, the possibility of a nail laceration or a compound fracture is present, and medical help should be sought immediately.

Over-the-counter (OTC) or prescription pain medication can be used to alleviate pain.

Alternatives

Acupuncture, therapeutic massage, and **yoga** are believed by some practitioners of alternative medicine to have generalized pain-relieving effects. Any of these therapies may provide additional comfort while the finger heals.

Prognosis

With proper treatment, most people regain full use of the affected finger. However, in some cases, although the finger regains its normal position, the person never regains full extension of the fingertip. In such cases, a deformity called "swan neck" results. While treatment is in progress, the device to hold the finger stationary sometimes causes a pressure sore over the distal interphalengeal joint. When damage to the bone or nail occurs, complications can result, such as stiffness, infection, and tenderness.

Prevention

There is not a specific way to prevent mallet finger, other than using extreme care and caution when performing routine activities and catching objects during sporting events and activities.

Mallory-Weiss syndrome

Definition

Mallory-Weiss syndrome is bleeding from an arterial blood vessel in the upper gastrointestinal tract, caused by a mucosal gastric tear at or near the point where the esophagus and stomach join.

Description

Mallory-Weiss syndrome causes about 5% of all upper gastrointestinal bleeding. The condition was originally diagnosed in alcoholics and is associated with heavy alcohol use, although it can also be found in patients who are not alcoholics. Earlier episodes of heavy hiccupping, **vomiting**, and retching are reported by about half the patients who are diagnosed with Mallory-Weiss syndrome. It is thought that the tear or laceration occurs when there is a sudden increase in intra-abdominal pressure. Patients with increased pressure in the vein leading into the liver (portal **hypertension**) are more likely to bleed heavily from an esophageal laceration than those whose blood pressure is normal.

WWW.BOOKBAZ.IR

KEY TERMS

Electrolytes—Salts and minerals that can conduct electrical impulses in the body. Common human electrolytes are sodium chloride, potassium, calcium, and sodium bicarbonate. Electrolytes control the fluid balance of the body and are important in muscle contraction, energy generation, and almost every major biochemical reaction in the body.

Endoscopy—A procedure in which an instrument containing a camera and a light source is inserted into the gastrointestinal tract so that the doctor can visually inspect the gastrointestinal system.

Esophageal varix—An enlarged vein of the esophagus. (Plural: esophageal varices.)

Portal hypertension—High blood pressure in the portal vein, which carries blood from the abdominal organs to the liver.

Causes and symptoms

In Mallory-Weiss syndrome, a tear occurs in the gastric mucosa, near where the esophagus and stomach join. About 10% of the tears are in the esophagus. Most are either right at the junction of the esophagus and stomach or in the stomach just slightly below the junction.

Bleeding from the tear causes a disruption in fluid and electrolyte balance of the body. The patient often produces vomit tinged with either fresh blood or older, blackish blood. Blood loss can be considerable.

Diagnosis

A Mallory-Weiss syndrome tear is not visible on standard upper gastrointestinal x rays. A tear about one-eighth to one and one-half inches long (0.5–4 cm) is revealed by **endoscopy**. Endoscopy also shows that in 35% of patients there is another potential cause for gastrointestinal bleeding, such as peptic ulcer, erosive **gastritis**, or esophageal varices.

Treatment

The patient is resuscitated and stabilized with blood transfusions and intravenous fluids to restore the fluid and electrolyte balance. Most of the time, esophageal bleeding stops spontaneously. When bleeding does not stop, patients are treated with an injection of epinephrine (adrenaline) and/or the bleeding artery is cauterized with heat. If these treatments fail, surgery is performed to stop the bleeding.

Prognosis

In 90-95% of patients whose bleeding does not stop spontaneously, cauterization without surgery will stop the bleeding. Patients at highest risk for a recurrence of bleeding are those with portal hypertension.

Prevention

Mallory-Weiss syndrome is associated with **alcoholism**. Limiting alcohol intake may help prevent the disorder.

Malnutrition

Definition

Malnutrition is the condition that develops when the body acquires a disproportionate, inadequate, or unbalanced amount of the **vitamins**, **minerals**, and other nutrients it needs to maintain healthy tissues and organ function. It may also develop when the body has problems digesting or absorbing nutrients, or has certain medical conditions. When malnutrition occurs, many different disorders may arise depending on the specific nutrient(s) involved in the malnutrition. One form of malnutrition is called **starvation**.

Demographics

Malnutrition is a major problem all over the world, but it is more likely to occur in the poorest countries of the world where natural disasters, political instabilities and wars, and poverty are more likely to be present. It is an exceptionally serious problem with infants, children, and adolescents because such nutrients are important during this period of extreme physical and mental growth. Malnutrition is estimated to occur in over 70% of children living in Asia, about 26% in Africa, and around 4% in Latin America and the Caribbean. In the United States, about 1% of children suffer from chronic malnutrition. According to the United Nations' Food Programme (UNFP), a child dies every six seconds somewhere in the world from malnutrition and related causes.

According to the United Nations Food and Agriculture Organization (FAO), approximately 1.02 billion people in the world are considered to be below standards provided by international nutritional guidelines, from data presented on October 14, 2009. This 2009 figure is greater than in 2006, when the number stood at 854 million. In this same period of time, it is estimated that poor **nutrition** was a contributing factor in approximately 5 million of the 10.9 million deaths each year of children.

Description

Undernutrition

Infants, young children, and teenagers need additional nutrients. So do women who are pregnant or **breastfeeding**. Nutrient loss can be accelerated by **diarrhea**, excessive sweating, heavy bleeding (hemorrhage), or kidney failure. Nutrient intake can be restricted by age–related illnesses and conditions, excessive dieting, **food allergies**, severe injury, serious illness, a lengthy hospitalization, or substance abuse.

For instance, someone who has an untreated medical disorder—such as **celiac disease** in which gluten (a protein found in barley, rye, and wheat) is not digestible; or **lactose intolerance**, in which milk and other dairy products are difficult to digest—is at a higher risk for malnutrition than someone without such disorders.

The leading cause of death in children in developing countries is protein-energy malnutrition. This type of malnutrition is the result of inadequate intake of calories from proteins, vitamins, and minerals. Children who are already undernourished can suffer from protein-energy malnutrition (PEM) when rapid growth, infection, or disease increases the need for protein and essential minerals. These essential minerals are known as micronutrients or trace elements. The World Health Organization (WHO) estimates that two billion people around the world do not consume sufficient amounts of iron in their daily diet. Iron is an important nutrient that is found in red meat, eggs, and foods fortified with iron.

Two types of protein-energy malnutrition have been described—kwashiorkor and marasmus. Kwashiorkor occurs with fair or adequate calorie intake but inadequate protein intake, while marasmus occurs when the diet is inadequate in both calories and protein. A kwashiorkor diet may consist of only vegetables. In such cases, a wide variety of vegetables is needed to obtain all the necessary nutrients in one's diet. With a marasmus diet the body may receive so little protein that it eventually cannot digest any protein, with irreversible and fatal results.

Overnutrition

In the United States, nutritional deficiencies have generally been replaced by dietary imbalances or excesses associated with many of the leading causes of death and disability. Overnutrition results from eating too much, eating too many of the wrong foods, not exercising enough, or taking too many vitamins or other dietary replacements.

Risk of overnutrition is also increased by being more than 20% overweight, consuming a diet high in fat and salt, and taking high doses of the following:

- Nicotinic acid (niacin) to lower elevated cholesterol levels
- Vitamin B_6 to relieve premenstrual syndrome
- Vitamin A to clear up skin problems
- Iron or other trace minerals not prescribed by a doctor

Nutritional disorders can affect any system in the body and the senses of sight, taste, and smell. They may also produce **anxiety**, changes in mood, and other psychiatric symptoms. Malnutrition begins with changes in nutrient levels in blood and tissues. Alterations in enzyme levels, tissue abnormalities, and organ malfunction may be followed by illness and death.

Causes and symptoms

Causes

Poverty and lack of food are the primary reasons why malnutrition occurs in the United States. Ten percent of all members of low–income households do not always have enough healthful foods to eat. Protein-energy malnutrition occurs in 50% of surgical patients and in 48% of all other hospital patients.

Another cause of malnutrition is loss of appetite associated with the **aging** process. Malnutrition affects one in four elderly Americans, in part because they may lose interest in eating. In addition, such dementia-type illnesses as Alzheimer's disease may cause elderly persons to forget to eat.

There is an increased risk of malnutrition associated with chronic diseases, especially disease of the intestinal tract, kidneys, and liver. Patients with chronic diseases like cancer, acquired immune deficiency syndrome (**AIDS**), intestinal parasites, and other gastric disorders may lose weight rapidly and

WWW.BOOKBAZ.IR

become susceptible to undernourishment because they cannot absorb valuable vitamins, calories, and iron.

People with drug or alcohol dependencies are also at increased risk of malnutrition. These people tend to maintain inadequate **diets** for long periods of time, and their ability to absorb nutrients is impaired by the alcohol or drug's affect on body tissues, particularly the liver, pancreas, and brain.

Eating disorders are another cause of malnutrition. People with anorexia or bulimia may restrict their food intake to such extremes that they become malnourished.

Food **allergies** may also lead to malnutrition. Some people with food allergies may find it difficult to obtain food that they can digest. In addition, people with food allergies often need additional calorie intake to maintain their weight.

Failure to absorb nutrients in food following bariatric (weight loss) surgery are yet another cause of malnutrition. **Bariatric surgery** includes such techniques as stomach stapling (gastroplasty) and various intestinal bypass procedures to help people eat less and lose weight. Malnutrition is, however, a possible side effect of bariatric surgery.

Symptoms

Unintentionally losing 10 pounds (4.5 kilograms of mass) or more in weight may be a sign of malnutrition. Malnourished people may appear to be skinny or bloated. Their skin is pale, thick, dry, and **bruises** easily. **Rashes** and changes in pigmentation are common.

Hair is thin, tightly curled, and pulls out easily. Joints ache and bones are soft and tender. The gums bleed easily, and they are swollen. The tongue may be swollen or shriveled and cracked. Visual disturbances include night blindness and increased sensitivity to light and glare.

Symptoms may vary depending on the specific cause of the malnutrition. However, some other general symptoms of malnutrition include:

- anemia
- fatigue
- diarrhea
- disorientation and dizziness
- fragile bones, osteoporosis
- irritability, anxiety, and attention deficits
- goiter (enlarged thyroid gland)
- loss of reflexes and lack of muscular coordination
- muscle twitches
- poor immune function (which hinders the body' ability to fight infections)
- difficulty learning
- slow growth, both physically and mentally, in children
- amenorrhea (cessation of menstrual periods)
- scaling and cracking of the lips and mouth
- dry, scaly skin
- bloated stomach

Malnourished children may be short for their age, thin, listless, and have weakened immune systems.

Diagnosis

Overall appearance, behavior, body-fat distribution, and organ function can alert a family physician, internist, or nutrition specialist to the presence of malnutrition. Patients may be asked to record what they eat during a specific period. X rays can determine bone density and reveal gastrointestinal disturbances, and heart and lung damage.

Blood and urine tests are used to measure the patient's levels of vitamins, minerals, and waste products. Nutritional status can also be determined by:

- Comparing a patient's weight to standardized charts
- Calculating body mass index (BMI) according to a formula that divides height into weight
- Measuring skin-fold thickness or the circumference of the upper arm

Treatment

Normalizing nutritional status starts with a nutritional assessment. This process enables a clinical nutritionist or registered dietician to confirm the presence of malnutrition, assess the effects of the disorder, and formulate diets that will restore adequate nutrition.

Patients who cannot or will not eat, or who are unable to absorb nutrients taken by mouth, may be fed intravenously (**parenteral nutrition**) or through a tube inserted into the gastrointestinal (GI) tract (enteral nutrition).

Tube feeding is often used to provide nutrients to patients who have suffered **burns** or who have inflammatory bowel disease. This procedure involves inserting a thin tube through the nose and carefully guiding it along the throat until it reaches the stomach or small intestine. If long-term tube feeding is necessary, the tube may be placed directly into the stomach or small intestine through an incision in the abdomen.

Tube feeding cannot always deliver adequate nutrients to patients who

- are severely malnourished
- require surgery
- are undergoing chemotherapy or radiation treatments
- have been seriously burned
- have persistent diarrhea or vomiting
- whose gastrointestinal tract is paralyzed

Intravenous feeding can supply some or all of the nutrients these patients need.

Prognosis

The prognosis for malnutrition depends directly on its cause. Most cases of malnutrition can be corrected. However, if the cause is an illness, then the condition must be first eliminated so that the patient can completely recover from malnutrition. In some cases, the damage done by malnutrition may be irreversible even though it is not severe enough to cause death. Up to 10% of a person's body weight can be lost without side effects, but if more than 40% is lost, the situation is almost always fatal. Death usually results from **heart failure**, electrolyte imbalance, or low body temperature. Patients with semi–consciousness, persistent diarrhea, **jaundice**, or low blood **sodium** levels have a poorer prognosis.

Some children with protein–energy malnutrition recover completely. Others have many health problems throughout life, including **intellectual disability** (ID) and the inability to absorb nutrients through the intestinal tract. Prognosis for all patients with malnutrition seems to be dependent on the age of the patient, and the length and severity of the malnutrition, with young children and the elderly having the highest rate of long–term complications, including both physical and mental disabilities and illnesses, and death.

Prevention

Breastfeeding a baby for at least six months is considered the best way to prevent early-childhood malnutrition. The U.S. Department of Agriculture and the Department of Health and Human Services recommend that all Americans over the age of two years:

- Consume plenty of fruits, grains, and vegetables
- Eat a well–balanced variety of foods that are low in fats and cholesterols and contain only moderate amounts of salt, sugars, and sodium
- Engage in moderate physical activity for at least 30 minutes, at least several times a week
- Achieve or maintain their ideal weight
- Use alcohol sparingly or avoid it altogether

Every patient admitted to a hospital should be screened for the presence of illnesses and conditions that could lead to protein–energy malnutrition. Patients with higher–than–average risk for malnutrition should be more closely assessed and reevaluated often during long–term hospitalization or nursing-home care.

KEY TERMS

Anemia—Not enough red blood cells in the blood.

Anorexia nervosa—Eating disorder marked by malnutrition and weight loss, commonly occurring in young women.

Bariatric—Pertaining to the study, prevention, or treatment of overweight.

Calorie—A unit of heat measurement used in nutrition to measure the energy value of foods. A Calorie is the amount of heat energy needed to raise the temperature of 1 kilogram of water 1°C.

Kwashiorkor—Severe malnutrition in children primarily caused by a protein–poor diet, characterized by growth retardation.

Marasmus—Severe malnutrition in children caused by a diet lacking in calories as well as protein. Marasmus may also be caused by disease and parasitic infection.

Micronutrients—Essential dietary elements that are needed only in very small quantities. Micronutrients are also known as trace elements. They include copper, zinc, selenium, iodine, magnesium, iron, cobalt, and chromium.

Malocclusion

Definition

Malocclusion is a misalignment in the way the upper and lower sets of teeth fit together in biting or chewing. The word *malocclusion* literally means "bad bite." The condition may also be referred to with such terms as irregular bite, misaligned teeth, crossbite, underbite, or overbite. American dentist and orthodontist Edward Angle (1855–1930) was the first scientist to classify malocclusion.

This patient's teeth are misarranged because of excessive thumb sucking. *(Custom Medical Stock Photo, Inc.)*

Demographics

Most humans have various tiny degrees of malocclusion, with most problems being handed down from generation to generation (hereditary). Their problem is not very noticeable and does not usually need to be treated. However, others have more serious forms of malocclusion; often times require orthodontic or surgical treatment.

Description

Occlusion refers to the alignment of teeth, specifically the way that the upper set of teeth fit slightly over the lower set of teeth. Malocclusion occurs when there is a misalignment of these two rows of teeth. Misalignment can occur when the upper jaw is a different size from the lower jaw or when the size of the jaws does not accommodate the size of the teeth. As a result, the teeth become crooked, crowded, or protrude. It may affect a person's appearance, speech, and/or ability to eat.

Three different classes of malocclusion generally occurs. They are:

- Neutroclusion: The bite of the two rows of teeth is normal but the upper teeth overlap the lower teeth more than usual, which causes problems such as overcrowding or incorrect spacing of the teeth.
- Distocclusion (retrognathism or "overbite"): The upper jaw and its teeth overlap the bottom jaw and its teeth.
- Mesiocclusio (prognathism or "underbite"): The lower jaw protrudes forward, which causes the lower jaw and its teeth to overlap the upper jaw and its teeth.

Causes and symptoms

Malocclusions are most often inherited, but may be acquired. Inherited conditions include too many or too few teeth, too much or too little space between teeth, irregular mouth and jaw size and shape, and atypical formations of the jaws and face, such as a **cleft palate**. Malocclusions may be acquired from habits like finger or thumb sucking (or pacifier use), tongue thrusting, premature loss of teeth from an accident or dental disease, and medical conditions such as enlarged tonsils and adenoids that lead to mouth breathing.

Orthodontia treatments usually include the use of braces and retainers. *(© Lester V. Bergman/Corbis.)*

They may also occur due to incorrectly fitting **dental fillings**, appliances, retainers, and other devices worn on the teeth. Other causes include an abnormal structure to the face, **pain** or other discomfort while biting and chewing, and difficulties with speaking or breathing.

Malocclusions may be symptomless or they may produce pain from increased **stress** on the oral structures. Teeth may show abnormal signs of wear on the chewing surfaces or decay in areas of tight overlap. Chewing may be difficult.

Diagnosis

Malocclusion is most often found during a routine dental examination. A dentist will check a patient's occlusion by watching how the teeth make contact when the patient bites down normally. The dentist may ask the patient to bite down with a piece of coated paper between the upper and lower teeth; this paper will leave colored marks at the points of contact. When malocclusion is suspected, the dentist will commonly refer the patient to an orthodontist for further diagnosis and treatment. The orthodontist will take photographs and x rays of the face and mouth for further study. To confirm the presence and extent of malocclusion, the orthodontist makes plaster, plastic, or artificial stone models of the patient's teeth from impressions. These models duplicate the fit of the teeth and are very useful in treatment planning.

Treatment

Even though most people have minor forms of malocclusion, such cases are rarely treated by a medical professional. However, when it is more serious malocclusion may be remedied by orthodontic treatment; **orthodontics** is a specialty of dentistry that manages the growth and correction of dental and facial structures. Braces are the most commonly used orthodontic appliances in the treatment of malocclusion. Such measures are used to position teeth into a more normal alignment. According to the U.S. Bureau of Labor Statistics, about 5,000 orthodontists were practicing in the United States in 2008. At any given time, approximately 4 million people in the United States are wearing braces, including about 800,000 adults.

Braces apply constant gentle force to slowly change the position of the teeth, straightening them and properly aligning them with the opposing teeth. Braces consist of brackets cemented to the surface of each tooth and wires of stainless steel or nickel titanium alloy. When the wires are threaded through the brackets, they exert pressure against the teeth, causing them to move gradually.

Invisalign® is an alternative to traditional braces and can also be used to correct malocclusion. Invisalign is a series of clear aligners that are worn to shift and straighten teeth gradually. Each aligner is custom made for the wearer and changed every two weeks to slowly shift teeth into correct alignment.

Braces are not removable for daily tooth brushing, so the patient must be especially diligent about keeping the mouth clean and removing food particles which become easily trapped, to prevent **tooth decay**. Crunchy foods should be avoided to minimize the risk of breaking the appliance. Hard fruits, vegetables, and breads must be cut into bite-sized pieces before eating. Foods that are sticky, including chewing gum, should be avoided because they may pull off the brackets or weaken the cement. Carbonated beverages may also weaken the cement, as well as contribute to tooth decay. Teeth should be brushed immediately after eating sweet foods. Special floss threaders are available to make flossing easier.

If overcrowding is creating malocclusion, one or more teeth may be extracted (surgically removed), giving the others room to move. If a tooth has not yet erupted or is prematurely lost, then the orthodontist may insert an appliance called a space maintainer to keep the other teeth from moving out of their natural position. In severe cases of malocclusion, surgery may be necessary and the patient would be referred to yet another specialist, an oral or maxillofacial surgeon.

WWW.BOOKBAZ.IR

Once the teeth have been moved into their new position, the braces are removed and a retainer is worn until the teeth stabilize in that position. Retainers do not move teeth, they only hold them in place.

Orthodontic treatment is the only effective treatment for malocclusion not requiring surgery. However, depending on the cause and severity of the condition, an orthodontist may be able to suggest other appliances as alternatives to braces.

Alternatives

There are some techniques of **craniosacral therapy** that can alter structure. This therapy may allow correction of some cases of malocclusion. If surgery is required, pre- and post-surgical care with homeopathic remedies, as well as vitamin and mineral supplements, can enhance recovery. Night guards are sometimes recommended to ease the strain on the jaw and to limit teeth grinding.

Prognosis

Depending on the cause and severity of the malocclusion and the appliance used in treatment, a patient may expect correction of the condition to take two or more years. Patients typically wear braces 18 to 24 months and a retainer for another year. Treatment is faster and more successful in children and teens whose teeth and bones are still developing. The length of treatment time is also affected by how well the patient follows orthodontic instructions. When malocclusion is corrected, it usually reduces the risk from tooth decay, along with helping to relieve undue pressure on the temporomandibular joint (TMJ), which can cause TMJ disorder (TMD). However, then treatment is applied to someone with malocclusion, specifically with braces, there may be some discomfort during the treatment. Irritation of the gums and mouth may result from the appliances on the teeth. Sometimes chewing or speaking may be adversely affected.

Prevention

In general, malocclusion is not preventable. It may be minimized by controlling habits such as finger or thumb sucking. An initial consultation with an orthodontist before a child is seven years old may lead to appropriate management of the growth and development of the child's dental and facial structures, circumventing many of the factors contributing to malocclusion.

KEY TERMS

Braces—An orthodontic appliance consisting or brackets cemented to the surface of each tooth and wires of stainless steel or nickel titanium alloy. Braces are used to treat malocclusion by changing the position of the teeth.

Impression—An imprint of the upper or lower teeth made in a pliable material that sets. When this material has hardened, it may be filled with plaster, plastic, or artificial stone to make an exact model of the teeth.

Occlusion—The way the upper and lower teeth fit together in biting or chewing.

Retainer—An orthodontic appliance that is worn to stabilize teeth in a new position.

Space maintainer—An orthodontic appliance that is worn to prevent adjacent teeth from moving into the space left by an unerupted or prematurely lost tooth.

MALT lymphoma

Definition

MALT lymphomas are solid tumors that originate from cancerous growth of immune cells that are recruited to secretory tissue such as the gastrointestinal tract, salivary glands, lungs, and the thyroid gland.

Description

The digestive tract is generally not associated with lymphoid tissue, with the exception of small collections of lymphocytes such as Peyer's patches. A specific kind of white blood cell, B-lymphocytes, can accumulate in response to infections of the digestive tract and other secretory tissues, or as a result of autoimmune conditions such as Sjgren's syndrome. When the growth of these lymphocytes is maintained through continued infection or autoimmune disease, a malignant cell can arise and replace the normal lymphocytes. These lymphomas, derived from mucosa-associated lymphoid tissue (MALT), most commonly arise in the stomach. Their growth seems to be dependent upon continuous stimulation of the immune system by an infectious agent, such as H. pylori, or some other entity, termed an antigen, that the body recognizes as foreign. This antigen-driven growth permits these tumors to be treated by eliminating the stimulus that generated the original, normal immune response. In the stomach they are associated, in greater than 90% of all cases, with the bacteria called Helicobacter pylori (H. pylori). This bacteria is also associated with peptic stomach irritation, **ulcers**, and gastric cancer. MALT lymphomas are generally indolent, that is, they grow slowly and cause little in the way of symptoms. Those MALT lymphomas that arise in the stomach in response to H. pylori infections are generally successfully treated with **antibiotics**, which eliminate the bacteria.

Demographics

MALT lymphomas occur at a frequency of about 1.5 per 100,000 people per year in the United States and account for about 10% of all non-Hodgkin's lymphomas. The frequency varies among different populations. For example, in parts of Italy the frequency of MALT lymphomas is as high as 13 per 100,000 people per year. This can in part be attributed to different rates of infection with H. pylori. However, other hereditary, dietary, or environmental factors are almost certainly involved.

Causes and symptoms

The majority of MALT lymphomas appear to be the result of infectious agents, most commonly H. pylori in the stomach. It is not known if infectious agents also cause MALT lymphomas outside of the stomach. In some cases, such as in the thyroid, MALT lymphomas seem to arise in patients who have autoimmune diseases, which make their immune systems treat their own tissue as foreign or antigenic. It is believed that there must be additional factors, in addition to infection or autoimmunity, that influence the development of MALT lymphomas. For example, in the United States, where infections with H. pylori are quite common, less than 1 in 30,000 people who have H. pylori in their stomachs develop MALT lymphomas. In addition, individuals who develop MALT lymphomas are more likely to develop other forms of cancer. This would suggest that there might be genetic factors predisposing individuals to develop MALT lymphomas or other tumors in response to environmental or infectious agents.

In general, patients have stomach **pain**, ulcers, or other localized symptoms, but rarely do they suffer from systemic complaints such as **fatigue** or **fever**.

Diagnosis

The indolent nature of most MALT lymphomas means that the majority of patients are diagnosed at early stages with relatively nonspecific symptoms. In the case of gastric MALT lymphomas, the physician will then have a gastroenterologist perform an **endoscopy** to examine the interior of the stomach. MALT lymphomas are then recognized as areas of inflammation or ulceration within the stomach. It is unusual for masses recognizable as tumors to be seen upon examination. Definitive diagnosis of MALT lymphoma requires a biopsy, in which a bit of tissue is removed from the stomach or other involved site. Examination of this tissue by a pathologist is the first step in distinguishing among the possible diagnoses of inflammation, indolent lymphoma, or a more aggressive form of cancer, such as gastric cancer or a rapidly growing non-Hodgkin's lymphoma. The pathologist evaluates the type of lymphoid cells that are present in the biopsy to establish the nature of the lesion. In addition, it is essential that the pathologist determine whether or not the lymphoma has grown beyond the borders of the mucosa, which lines the stomach or other gland.

Treatment

The best staging system to employ for MALT lymphomas is still the subject of discussion. However,

KEY TERMS

Antigen—A foreign substance that leads to an immune response, including the production of antibodies by B cells.

Autoimmune disease—A condition in which an individual's immune system reacts to the person's own tissues, viewing self components as if they were foreign antigens.

Bone marrow biopsy—A procedure in which cellular material is removed from the pelvis or breastbone and examined under a microscope to look for the presence of abnormal blood cells characteristic of specific forms of leukemia and lymphoma.

Indolent lymphoma (also called low-grade lymphoma)—Cancerous growths of lymphoid tissue that progress slowly to more aggressive forms of cancer.

Lymphoid tissue—Sites within the body that produce cells of the immune system, including lymph nodes, bone marrow, and the thymus.

it is standard practice that patients presenting with MALT lymphomas should be evaluated in a similar manner to individuals with nodal lymphomas, the more common type of lymphoma that originates at sites within the lymphoid system. These procedures include a complete history and physical, blood tests, chest x rays, and bone marrow biopsy. This evaluation will permit the oncologist to determine if the disease is localized or if it has spread to other sites within the body.

In general, the prognosis for patients with MALT lymphomas is good, with overall five-year survival rates that are greater than 80%. The features that are most closely related to the outlook for newly diagnosed individual patients are: whether the primary site is in the stomach or is extra-gastric; if the disease has spread beyond the initial location; and whether the histologic evaluation of the initial tumor biopsies is consistent with a low-grade, slowly growing lesion, as compared to a high-grade lesion that is more rapidly growing. In general, the histologic grade is the most important feature, with high-grade lesions requiring the most aggressive treatment.

Treatment of MALT lymphomas differs from that of most lymphomas. In the most common type of MALT lymphomas—low-grade lesions originating in the stomach—treatment with antibiotics to eliminate H. pylori leads to complete remissions in the majority of patients. The effectiveness of this treatment is indistinguishable from surgery, **chemotherapy**, **radiation therapy**, or a combination of surgery with drugs or irradiation. Approximately one-third of patients in this group have evidence of disseminated disease, where lymphoma cells are detected at sites in addition to the gastric mucosa. The response of these patients to antibiotic treatment is not significantly different from that for individuals with localized disease. For both groups a complete remission is achieved in about 75% of patients, who remain, on average, free of disease for about 5 years.

Prognosis

Patients with MALT lymphomas arising outside of the digestive tract also have good prognoses. Effective treatment for these lymphomas has been achieved with local radiation, chemotherapy, and/or interferon. Surgery followed by chemotherapy or radiation is also effective with nongastrointestinal MALT lymphomas. Overall these patients have five-year survival rates greater than 90%.

While the outlook for patients with MALT lymphomas is good, difficulties in diagnosis and staging have left the optimal treatment a matter of continued study. This is an especially open question for those patients who fail to respond to antibiotic therapy, or whose disease recurs. It may be the case that in these patients, the MALT lymphoma may have already progressed to a point where high-grade lesions, not observed in the original biopsies, were resistant to the initial treatment. The best treatment for these patients remains to be established. In general, these patients are treated with chemotherapy in a similar manner to patients with other types of lymphoma. Given the success of antibiotics, and the good prognosis for gastric MALT lymphomas in general, no sufficient body of evidence exists to determine the best chemotherapy for patients who fail to achieve a complete and lasting remission upon initial treatment. At present, a chemotherapeutic regime designated CHOP includes the anti-cancer drugs cyclophosphamide, doxorubicin, vincristine, and prednisone. Similar drug combinations are being used for patients whose MALT lymphomas do not respond to antibiotic treatment.

Clinical trials have concentrated on optimizing treatment of gastric MALT lymphomas that involve H. pylori. The aspects of treatment being addressed are the most effective antibiotics and the use of **antacids** to modulate irritation in the stomach. These protocols have been designed to follow the natural history of gastric lymphomas and to establish the biological features that predict treatment response to antibiotics and duration of remission.

Prevention

There are no commonly accepted means to prevent MALT lymphomas. While the H. pylori infections are associated with this and other gastric disease, the eradication of H pylori in asymptomatic individuals is not currently recommended for prevention of MALT lymphomas or gastric cancer.

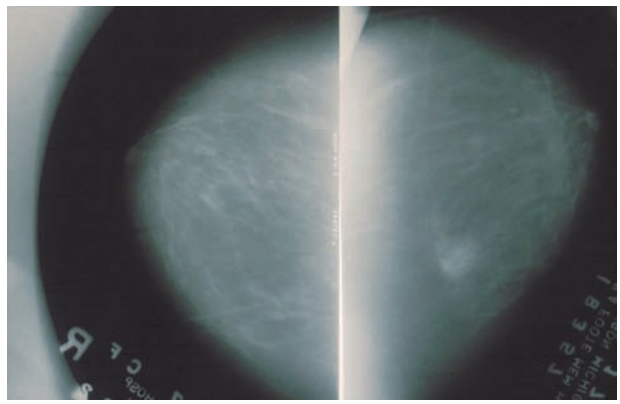
Mammography

Definition

Mammography is the study of the breast using x rays. The actual test is called a mammogram. It is an x ray of the breast that shows the fatty, fibrous, and glandular tissues. There are two types of mammograms: screening and diagnostic. A screening mammogram is ordered for women who have no problems with their breasts. It consists of two x ray views of each breast: a craniocaudal (from above) and a mediolateral oblique (from the sides). A diagnostic mammogram is for evaluation of abnormalities in either men or women. Additional x rays from other angles, or special coned views of certain areas, are taken.

Purpose

The purpose of screening mammography is **breast cancer** detection. A screening test by definition is used for patients without any signs or symptoms in order to detect disease as early as possible. Many studies have shown that having regular mammograms increases a woman's chances of finding breast cancer in an early stage, when it is more likely to be curable. It has been estimated that a mammogram may find a cancer as much as two or three years before it can be felt. The American Cancer Society (ACS) guidelines recommend an annual screening mammogram for every woman of average risk beginning at age 40. Radiologists look specifically for the presence of microcalcifications and other abnormalities that can be associated with malignancy. New digital mammography and computer-aided reporting can automatically enhance and magnify the mammograms for easier identification of these tiny calcifications.



Comparison of two mammograms—cancerous tissue is shown on right and normal tissue on left. *(Custom Medical Stock Photo, Inc.)*

The highest risk factor for developing cancer is age. Some women are at an increased risk for developing breast cancer, such as those with a positive family history of the disease. Beginning screening mammography at a younger age may be recommended for these women.

Diagnostic mammography is used to evaluate an existing problem, such as a lump, discharge from the nipple, or unusual tenderness in one area. It is also done to evaluate further abnormalities that have been seen on screening mammograms. The radiologist normally views the films immediately and may ask for additional views, such as a magnification of one specific area. Additional studies such as an **ultrasound** of the breast may be performed as well to determine whether the lesion is cystic or solid. Breast-specific **positron emission tomography** (PET) and **magnetic resonance imaging** (MRI) scans may be ordered to further evaluate a tumor, but mammography is still the first choice in detecting small tumors on a screening basis.

WWW.BOOKBAZ.IR

A person undergoing a mammography. *(Custom Medical Stock Photo, Inc.)*

Description

A mammogram may be offered in a variety of settings. Hospitals, outpatient clinics, physician's offices, or other facilities may have mammography equipment. In the United States, only places certified by the U.S. Food and Drug Administration (FDA) are legally permitted to perform, interpret, or develop mammograms. Mammograms are taken with dedicated machines using high frequency generators, low kVp (kilovolts peak), molybdenum targets, and specialized x ray beam filtration. Sensitive high-contrast film and screen combinations along with prolonged developing enable the visualization of minute breast details.

In addition to the usual paperwork, a woman will be asked to fill out a questionnaire asking for information on her current medical history. Beyond her personal and family history of cancer, details about menstruation, previous breast surgeries, child bearing, birth control, and **hormone replacement therapy** are recorded. Information about **breast self-examination** (BSE) and other breast health issues are usually available at no charge.

At some centers, a technologist may perform a **physical examination** of the breasts before the mammogram. Whether or not this is done, it is essential for the technologist to record any lumps, nipple discharge, breast **pain**, or other concerns of the patient. All visible **scars**, tattoos, and nipple alterations must be carefully noted as well.

Clothing from the waist up is removed, along with necklaces and dangling earrings. A hospital gown or similar covering is put on. A small self-adhesive metal marker may be placed on each nipple by the x-ray technologist. This allows the nipple to be viewed as a reference point on the film for concise tumor location and easier centering for additional views. Large **moles** within the mammography field may be covered in the same way.

Patients are positioned for mammograms differently, depending on the type of mammogram being performed:

- For craniocaudal position (CC), the woman stands or sits facing the mammogram machine. One breast is exposed and raised to a level position while the height of the cassette holder is adjusted to the same level. The breast is placed mid-film with the nipple in profile and the head turned away from the side being x-rayed. The shoulder is relaxed and pulled slightly backward while the breast is pulled as far forward as possible. The technologist holds the breast in place and slowly lowers the compression with a foot pedal. The breast is compressed between the film holder and a rectangle of plastic (called a paddle). The breast is compressed until the skin is taut and the breast tissue firm when touched on the lateral side. The exposure is taken immediately and the compression released. Good compression can be uncomfortable, but it is necessary. Compression reduces the thickness of the breast, creates a uniform density, and separates overlying tissues. This allows for a detailed image with a lower exposure time and decreased radiation dose to the patient. The same view is repeated on the opposite breast.
- For mediolateral oblique position (MLO), the woman is positioned with her side toward the mammography unit. The film holder is angled parallel to the pectoral muscle, anywhere from 30 to 60 degrees depending on the size and height of the patient. The taller and thinner the patient, the higher the angle. The height of the machine is level with the axilla (armpit). The arm is placed at the top of the cassette holder with a corner touching the armpit. The breast is lifted forward and upward, and compression is applied until the breast is held firmly in place by the paddle. The nipple should be in profile and the opposite breast held away by the patient, if necessary. This procedure is repeated for the other breast. A total of four

x rays, two of each breast, are taken for a screening mammogram. Additional x rays, using special paddles, different breast positions, or other techniques may be taken for a diagnostic mammogram.

The mammogram may be seen and interpreted by a radiologist right away, or it may not be reviewed until later. If there is any questionable area or abnormality, extra x rays may be recommended. These may be taken during the same appointment. More commonly, especially for screening mammograms, the woman is called back on another day for these additional films.

A screening mammogram usually takes approximately 15 to 30 minutes. A woman having a diagnostic mammogram can expect to spend up to an hour for the procedure.

The cost of mammography varies widely. Many mammography facilities accept "self-referral." This means women can schedule themselves without a physician's referral. However, some insurance policies do require a doctor's prescription to ensure payment. Medicare covers annual screening mammograms for eligible women over age 40.

Preparation

The compression or squeezing of the breast necessary for a mammogram is a concern to many women. Mammograms should be scheduled when a woman's breasts are least likely to be tender. One to two weeks after the first day of the menstrual period is usually best, as the breasts may be tender during the menstrual period. Some women with sensitive breasts also find that stopping or decreasing **caffeine** intake from coffee, tea, colas, and chocolate for a week or two before the examination decreases any discomfort. Women receiving hormone therapy may also have sensitive breasts. Over-the-counter pain relievers are recommended an hour before the mammogram appointment when pain is a significant problem.

Women should not put deodorant, powder, or lotion on their upper body on the day the mammogram is performed. Particles from these products can get on the breast or film holder and may show up as abnormalities on the mammogram. Most facilities will have special wipes available for those patients who need to wash before the mammogram.

Aftercare

No special aftercare is required.

Risks

The risk of radiation exposure from a mammogram is considered minimal and not significant. Experts are unanimous that any negligible risk is by far outweighed by the potential benefits of mammography. Patients who have **breast implants** must be x-rayed with caution, and compression is minimally applied so that the sac is not ruptured. Special techniques and positioning skills must be learned before a technologist can x ray a patient with breast implants.

Some breast cancers do not show up on mammograms; they hide or "hide" in dense breast tissue. A normal (or negative) study is not a guarantee that a woman is cancer free. The false-negative rate is estimated to be 15%–20%, and even higher in younger women and women with dense breasts.

False positive readings are also possible. Breast biopsies may be recommended on the basis of a mammogram and find no cancer. It is estimated that 75%–80% of all breast biopsies result in benign (no cancer present) findings. This is considered an acceptable rate, because recommending fewer biopsies would result in too many missed cancers.

Results

A mammography report describes details about the x-ray appearance of the breasts. It also rates the mammogram according to standardized categories, as part of the Breast Imaging Reporting and Data System (BI-RADS) created by the American College of **Radiology** (ACR):

- BI-RADS 0 means that the x-ray scan was incomplete and additional imaging scans are needed.
- BI-RADS 1 is considered normal or negative and means that no abnormalities were seen.
- BI-RADS 2 is also considered normal but refers to benign findings. One or more abnormalities were seen in the breast but they were clearly benign (not cancerous) or variations of normal. Some kinds of calcifications, enlarged lymph nodes, or obvious cysts might generate a BI-RADS 2 rating.
- BI-RADS 3 means that either additional images are needed or that an abnormality was seen but is probably (but not definitely) benign. A follow-up mammogram within a short interval of 6 to 12 months is suggested. This helps to ensure that the abnormality is not changing, or is "stable." Only the affected side will be x-rayed at this time. Some women are uncomfortable or anxious about waiting, and may

Benign—Noncancerous.

Breast biopsy—A procedure in which suspicious tissue is removed and examined by a pathologist for cancer or other disease. The breast tissue may be obtained by open surgery or through a needle.

Craniocaudal—Head-to-tail x-ray beam directly overhead the part being examined.

Magnetic resonance imaging (MRI)—An imaging technique that uses magnetic fields and computers to create detailed cross-sectional pictures of the interior of the body.

Malignant—Cancerous.

Radiographically dense—Having an abundance of glandular tissue that results in diminished anatomic detail on the mammogram.

Ultrasound—A technique that uses high-frequency sound waves to create a visual image (a sonogram) of soft tissues in the body.

want to consult with their doctor about having a biopsy.

- BI-RADS 4 means suspicious for cancer. A biopsy is usually recommended in this case.
- BI-RADS 5 means an abnormality is highly suggestive of cancer. A biopsy or other appropriate action should be taken.
- BI-RADS 6 refers to lesions that have been confirmed as malignant.

There are also ratings for breast density:

- BI-RADS 1 means that the breast is mostly fat (75% or more).
- BI-RADS 2 means that 25%–50% of the breast is fibrous and glandular tissue.
- BI-RADS 3 indicates that up to 75% of the breast is dense fibrous or glandular tissue, which can make it difficult to detect small masses.
- BI-RADS 4 means that more than 75% of the breast is fibrous or glandular tissue, which can potentially lead to a missed diagnosis.

Screening mammograms are not usually recommended for women under age 40 who have no special risk factors and normal physical breast examinations. A mammogram may be useful if a lump or other problem is discovered in a woman aged 30–40. Below age 30, breasts tend to be "radiographically dense," which means that the breasts contain a large amount of glandular tissue that is difficult to image in fine detail. Mammograms for this age group are controversial. An ultrasound of the breasts is usually done instead.

Mania

Definition

Mania is an abnormally elated mental state, typically characterized by feelings of euphoria, lack of inhibitions, racing thoughts, diminished need for sleep, talkativeness, risk taking, and irritability. In extreme cases, mania can induce **hallucinations** and other psychotic symptoms.

Description

Mania typically occurs as a symptom of **bipolar disorder** (a mood disorder characterized by both manic and depressive episodes). Individuals experiencing a manic episode often have feelings of self-importance, elation, talkativeness, sociability, and a desire to embark on goal-oriented activities, coupled with the less desirable characteristics of irritability, impatience, impulsiveness, hyperactivity, and a decreased need for sleep. (Hypomania is a term applied to a condition resembling mania. It is characterized by persistent or elevated expansive mood, hyperactivity, inflated self esteem, etc., but of less intensity than mania.) Severe mania may have psychotic features.

Causes and symptoms

Mania can be induced by the use or abuse of stimulant drugs such as cocaine and amphetamines. It is also the predominant feature of bipolar disorder, or manic depression, an affective mental illness that causes radical emotional changes and mood swings.

The Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (*DSM–IV*), the diagnostic standard for mental health professionals in the United States, describes a manic episode as an abnormally elevated mood lasting at least one week that is distinguished by at least three of the following symptoms: inflated self-esteem, decreased need for sleep, talkativeness, racing thoughts, distractibility, increase in goal-directed activity, or excessive involvement in pleasurable activities that have a high potential for painful consequences. If the mood of the patient is irritable and not elevated, four of these symptoms are required.

Diagnosis

Mania is usually diagnosed and treated by a psychiatrist and/or a psychologist in an outpatient setting. However, most severely manic patients require hospitalization. In addition to an interview, several clinical inventories or scales may be used to assess the patient's mental status and determine the presence and severity of mania. An assessment commonly includes the Young Mania Rating Scale (YMRS). The Mini-Mental State Examination (MMSE) may also be given to screen out other illnesses such as **dementia**.

Treatment

Mania is treated primarily with drugs. The following mood–stabilizing agents are commonly prescribed to regulate manic episodes:

- Lithium (Cibalith–S, Eskalith, Lithane) is one of the oldest and most frequently prescribed drugs available for the treatment of mania. Because the drug takes four to seven days to reach a therapeutic level in the bloodstream, it is sometimes prescribed in conjunction with neuroleptics (antipsychotic drugs) and/or benzodiazepines (tranquilizers) to provide more immediate relief of mania.
- Carbamazepine (Tegretol, Atretol) is an anticonvulsant drug usually prescribed in conjunction with other mood–stabilizing agents. The drug is often used to treat bipolar patients who have not responded well to lithium therapy. Carbamazepine is also approved for the treatment of mania by the FDA.
- Valproate (divalproex sodium, or Depakote; valproic acid, or Depakene) is an anticonvulsant drug prescribed alone or in combination with carbamazepine

KEY TERMS

Bipolar disorder—Formerly called manic–depressive disorder. A mood disorder characterized by alternating periods of overconfidence and activity (manic highs) and depressive lows.

Hypomania—A less severe form of elevated mood state that is a characteristic of bipolar type II disorder.

Mixed mania—A mental state in which symptoms of both depression and mania occur simultaneously.

Psychiatrist—A medical doctor who has completed specialized training in the diagnosis and treatment of mental illness. Psychiatrists can diagnose mental illnesses, provide mental health counseling, and prescribe medications.

Psychologist—A mental health professional who treats mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth. Psychologists also study the brain, behavior, emotions, and learning.

Psychotherapy—The treatment of mental and behavioral disorders by support and insight to encourage healthy behavior patterns and personality growth.

and/or lithium. For patients experiencing "mixed mania," or mania with features of depression, valproate is preferred over lithium.

Clozapine (Clozaril) is an atypical antipsychotic medication used to control manic episodes in patients who have not responded to typical mood–stabilizing agents. The drug has also been a useful preventative treatment in some bipolar patients. Other new anticonvulsants (lamotrigine, gubapentin) are being investigated for treatment of mania and bipolar disorder.

Prognosis

Patients experiencing mania as a result of bipolar disorder require long-term care to prevent recurrence; bipolar disorder is a chronic condition that requires lifelong observation and treatment after diagnosis. Data show that almost 90% of patients who experience one manic episode will go on to have another.

Prevention

Mania as a result of bipolar disorder can only be prevented through ongoing pharmacologic treatment. Patient education in the form of therapy or self-help groups is crucial for training patients to recognize signs of mania and to take an active part in their treatment program. **Psychotherapy** is an important adjunctive treatment for patients with bipolar disorder.

Mantle cell lymphoma

Definition

Mantle cell lymphoma (MCL) is a rare type of non-Hodgkin's lymphoma (NHL) characterized under the

microscope by expansion of the mantle zone area of the lymph node with a homogeneous (structurally similar) population of malignant small lymphoid cells. These cancerous cells have slightly irregular nuclei and very little cytoplasm, and are mixed with newly made normal lymphocytes (white blood cells) that travel from the bone marrow to the lymph nodes and spleen. Unlike normal lymphocytes, they do not mature properly and become cancerous instead.

Demographics

Each year, mantle cell lymphoma cases are only about 6% of all NHL diagnoses. Mantle cell lymphoma is rare in persons under the age of 50. The average age of a patient with Mantle cell lymphoma is 65. Most patients are men; out of 1,000 persons diagnosed with MCL, approximately 33% will be women. This cancer has the shortest average survival of all lymphoma types.

Description

The body's immune system produces two types of lymphocytes or white blood cells: the B cells which are made in the bone marrow and the T cells which are made in the thymus. Both types of cells are found in the lymph, the clear liquid that bathes tissues and circulates in the lymphatic system. Lymphomas are cancers that occur in this lymphatic system and B-Cell lymphomas—also called non-Hodgkin's lymphomas—include follicular lymphomas, small non-cleaved cell lymphomas (Burkitt's lymphomas), marginal zone lymphomas (MALT lymphomas), small lymphocytic lymphomas, large cell lymphomas and also mantle cell lymphomas.

Mantle cell lymphoma accounts for 5% to 10% of all lymphomas diagnosed and 5% of B-cell lymphomas. There are three subsets of MCL cells: the mantle zone type, the nodular type, and the blastic or blastoid (immature) type. These various types often occur together to some degree, and approximately 30% to 40% of diagnoses are of mixed mantle and nodular type. As MCL develops further, the non-cancerous mantle centers also become invaded by cancerous cells. In about 20% of these cases, the cells become larger, and of the blastic type.

Extensive debates are ongoing concerning the grade of this cancer. European classification used to classify it as a low-grade cancer because it is initially slow-growing, while American classification considered it intermediate based on patients' shorter average survival rate. The combined European-American classification (REAL) is still debating the status of mantle cell lymphoma. This is due to the mixed nature of MCL cells. Blastic type-MCL seems to be considered as a high-grade cancer because it spreads at about the rate of other lymphomas belonging to that category. The studies currently attempting to describe the precise nature of these cells will be key to any general agreement that is finally reached.

Causes and symptoms

The cause of MCL appears to be breakage in chromosome 11. A small piece of chromosome 11 is then transferred to chromosome 14. About 85% of all MCL patients display this chromosomal abnormality.

As a result of this chromosomal abnormality (deemed a reciprocal translocation), B cell lymphoma cells produce abnormally large quantities of a protein that encourages rapid cell growth.

Many of its symptoms are shared by other lymphomas as well, and patients generally complain of fatigue, anemia, low grade fevers, night sweats, weight loss, rashes, digestive disturbances, chronic sinus irritation, recurrent infections, sore throat, shortness of breath, muscle and bone aches and edema.

More specific symptoms include spleen enlargement (in about 60–80% of cases), particularly with nodular-type MCL. Swollen lymph nodes are an early-stage symptom, even though the general health of the patient is good. Mild anemia is also common. Some patients also report lower back pain, and burning pain in the legs and testicles. As MCL becomes more advanced, the lymph nodes increase in volume, and the general symptoms become more pronounced.

In the end stage of MCL, neurologic symptoms appear, indicating that the MCL has spread to the central nervous system.

Diagnosis

MCL is very similar to several other lymphoma types, and special care must be taken with the diagnosis. It should not be made from blood or bone marrow specimens alone. It is believed that immunologic tests are required to make the correct diagnosis. Immunophenotyping is one such test, it is used to determine what kind of surface molecules are present on cells, and thus, the exact type of lymphoma from a tissue sample. The Lymphoma Research Foundation of America recommends that several opinions be sought from recognized mantle cell experts to confirm the accuracy of the diagnosis.

WWW.BOOKBAZ.IR

KEY TERMS

Anemia—A condition caused by a reduction in the amount of red blood cells produced by the bone marrow. Its symptoms are general weakness and lack of energy, dizziness, shortness of breath, headaches, and irritability.

Antibody—A protein (immunoglobulin) produced by plasma cells (mature B cells) to fight infections in the body. They are released into the circulatory system in response to specific antigens and thus target those antigens that induced their production.

Antigen—Any substance that elicits an antibody response. As such, they are substances that stimulate a specific immune response of the body and are capable of reacting with the products of that response. Antigens may be foreign chemical substances or proteins located on the surface of viruses, bacteria, toxins, tumors and other infectious agents.

B-Cell lymphocyte—A type of lymphocyte (white blood cell). B cells react to the presence of antigens by dividing and maturing into plasma cells.

B-cell lymphomas—Non-Hodgkin's lymphomas that arise from B cells.

Blood cell—Cellular component of blood. There are three general types: white blood cells, red blood cells, and platelets, all which are produced in the bone marrow.

Cytoplasm—The organized complex of organic and inorganic substances external to the nuclear membrane of a cell.

DNA—Deoxyribonucleic acid are nucleic acids that are the part of the cell nucleus that contains and controls all genetic information.

Edema—Swelling of a body part caused by an abnormal buildup of fluids.

Gene—The specific site on a chromosome, consisting of protein and DNA responsible for the transmittal and determination of hereditary characteristics.

Gene therapy—The use of genes to treat cancer and other diseases.

Immune system—The system within the body, consisting of many organs and cells, that recognizes and fights foreign cells and disease.

Lymph—A milky white liquid responsible for carrying the lymphocytes in the lymphatic vessels.

Lymphatic system—Tissues and organs such as the bone marrow, spleen, thymus and lymph nodes that produce and store cells to fight infection and disease. Also includes the lymphatic vessels that carry lymph.

Lymphocyte—A type of white blood cell that defends the body against infection and disease. Lymphocytes are found in the bloodstream, the lymphatic system, and lymphoid organs. The two main types of lymphocytes are the B cells (produced in the bone marrow) and the T cells (produced in the thymus).

Lymphoma—Cancers that start in the lymphatic system. Lymphomas are classified into two categories: Hodgkin's Disease and the non-Hodgkin's lymphomas.

Monoclonal antibody—An antibody raised against a specific antigen. Monoclonal antibodies are being used to target chemotherapy or radioactive substances directly to cancer cells.

Non-Hodgkin's lymphomas—Lymphomas characterized by different types of cancerous lymphatic cells, excluding those characterized by Hodgkin's disease.

Remission—A complete or partial disappearance of the signs and symptoms of cancer, usually in response to treatment.

Stem cell—Primitive cell found in the bone marrow and in the blood stream. Stem cells become different types of mature blood cells, thus enabling them to rejuvenate the circulatory and immune systems.

Stem cell transplant—Treatment procedure by which young blood stem cells are collected from the patient (autologous) or another matched donor (allogeneic). High-dose chemotherapy and/or radiation is given, and the stem cells are reinserted into the body to rebuild the patient's immune system.

At the time of diagnosis, mantle cell lymphoma has usually spread into other tissues such as the lymph nodes, spleen, bone marrow (up to 90% of cases), or to Waldeyer's ring (the ring of adenoid, palatine and lingual tonsils at the back of the mouth) or to the gastrointestinal tract. MCL can also spread to the colon, in which case it is diagnosed as multiple lymphomatous polyposis.

Treatment

There is no formal staging system for mantle cell lymphoma and no standard treatment has yet been adopted for MCL patients. Patients have been treated with surgery, radiation, single drug or combination chemotherapy and stem cell transplants. CHOP is one of the most common chemotherapy regimens for treating MCL. Its name is an acronym for the combination of drugs used: Cyclophosphamide (cytoxan, neosar), adriamycin (doxorubicin or Hydroxydoxorubicin), vincristine (Oncovin), and Prednisone.

Alternatives

Because MCL is a cancer of the lymphatic system, immunologic therapies are often used, or combined with the more conventional radiation and chemotherapy treatments. Immunological therapies take advantage of the body's immune system. The immune system is a network of specialized cells and organs that defends the body against foreign invaders (antigens) by producing special "defense" proteins, an example of which are the antibodies. These substances recognize and attach to the antigens, usually found on the surface of cells and destroy them. There are reports of immunological therapies being used for MCL using interferon, one such natural substance produced by the body in response to a virus. Numerous studies show that interferons can stimulate the immune system to fight the growth of cancer, but there has not yet been enough evidence produced to see it emerge as a strong candidate for MCL treatment.

Other immunological therapies based on monoclonal antibodies (MABs or MOABs) have recently emerged, such as Rituxan (rituximab). MABs work on cancer cells in the same way natural antibodies work, by identifying and binding to the target cells, alerting other cells in the immune system to the presence of the cancer cells. MABs are very specific for a particular antigen, meaning that one designed for a B-cell lymphoma will not work on T-cell lymphomas. MABs used alone may enhance a patient's immune response to the cancer but they are thought to be more efficient when combined to another form of therapy, such as a chemotherapeutic drug. This way, the cancer is attacked on two fronts: chemical attack from the chemotherapy and immune response attack stimulated by the MAB.

Clinical trials

Clinical trials addressing the needs of MCL patients are very recent because the mantle cell lymphoma subtype has only recently been defined. There are now several trials being carried out in the United States specifically for mantle cell. Some other trials designed for patients with lymphomas may also accept mantle cell patients. Ongoing trials in this area are cheifly concerned with investigating monoclonal antibodies. Information regarding clinical trials can be obtained through the Clinical Trials web site listed at the end of this entry.

The following clinical protocols are specifically designed for MCL patients:

- The MD Anderson Protocol (high-dose chemotherapy with or without stem cell transplant)
- Rituxan, by itself or with CHOP
- Bexxar
- Oncolym
- Flavopiridol
- Phenylacetate

Prognosis

There is no cure for mantle cell lymphoma. As with other slow-growing lymphomas, spontaneous remissions have been reported. Unfortunately, the median survival rate is only three to four years. All mantle cell lymphoma experts agree that the long-term prognosis of MCL patients receiving conventional treatment is poor, and that there is an urgent need for new, improved therapies.

Prevention

Because the cause of MCL is unknown, no prevention measures can be recommended.

Coping with cancer treatment

It is important to have a caregiver system when receiving medical treatment for MCL, and it is just as important to have a network of support for coping with the non medical aspects of the cancer. Friends, relatives, coworkers and health professionals all can provide help, as well as the national cancer associations, some specifically addressing the needs of lymphoma patients.

Because MCL is a cancer that usually involves chemotherapy and radiation therapy, it can be severely damaging to organ function and long-term resistance. In addition to the immediate side effects of these treatments, other effects appear after treatment is completed, one of which, called Post-Cancer Fatigue (PCF), is often seen with lymphoma patients. This is fatigue that persists after treatment and can

WWW.BOOKBAZ.IR

sometimes be extreme. The medical team will be able to offer the best advice to deal with PCF.

Marfan syndrome

Definition

Marfan syndrome is an inherited disorder of the connective tissue that causes abnormalities of the patient's eyes, cardiovascular system, and musculoskeletal system. It is named for the French pediatrician, Antoine Marfan (1858–1942), who first described it in 1896. Marfan syndrome is sometimes called arachnodactyly, which means "spider-like fingers" in Greek, since one of the characteristic signs of the disease is disproportionately long fingers and toes. It is estimated that one person in every 3,000–5,000 has Marfan syndrome, or about 50,000 people in the United States. Marfan syndrome is one of the more common inheritable disorders.

Description

Marfan syndrome affects three major organ systems of the body: the heart and circulatory system, the bones and muscles, and the eyes. The genetic mutation responsible for Marfan was discovered in 1991. It affects the body's production of fibrillin, which is a protein that is an important part of connective tissue. Fibrillin is the primary component of the microfibrils that allow tissues to stretch repeatedly without weakening. Because the fibrillin is abnormal, the patient's connective tissues are looser than usual, which weakens or damages the support structures of the entire body.

The most common external signs associated with Marfan syndrome include excessively long arms and legs, with the patient's arm span being greater than his or her height. The fingers and toes may be long and slender, with loose joints that can be bent beyond their normal limits. This unusual flexibility is called hypermobility. The patient's face may also be long and narrow, and he or she may have a noticeable curvature of the spine. It is important to note, however, that Marfan patients vary widely in the external signs of their disorder and in their severity; even two patients from the same family may look quite different. Most of the external features of Marfan syndrome become more pronounced as the patient gets older, so that diagnosis of the disorder is often easier in adults than in children. In many cases, the patient may have few or very minor outward signs of the disorder, and the diagnosis may be missed until the patient develops vision problems or cardiac symptoms.

Marfan syndrome by itself does not affect a person's intelligence or ability to learn. There is, however, some clinical evidence that children with Marfan have a slightly higher rate of hyperactivity and attention-deficit disorder (ADD) than the general population. In addition, a child with undiagnosed nearsightedness related to Marfan may have difficulty seeing the blackboard or reading printed materials, and thus do poorly in school.

Marfan syndrome affects males and females equally, and appears to be distributed equally among all races and ethnic groups. The rate of mutation of the fibrillin gene, however, appears to be related to the age of the patient's father; older fathers are more likely to have new mutations appear in chromosome 15.

Causes and symptoms

Marfan syndrome is caused by a single gene for fibrillin on chromosome 15, which is inherited in most cases from an affected parent. Between 15 and 25% of cases result from spontaneous mutations. Mutations of the fibrillin gene (FBNI) are unique to each family

affected by Marfan, which makes rapid genetic diagnosis impossible, given present technology. The syndrome is an autosomal dominant disorder, which means that someone who has it has a 50% chance of passing it on to any offspring.

Another important genetic characteristic of Marfan syndrome is variable expression. This term means that the mutated fibrillin gene can produce a variety of symptoms of very different degrees of severity, even in members of the same family.

Cardiac and circulatory abnormalities

The most important complications of Marfan are those affecting the heart and major blood vessels; some are potentially life-threatening. About 90% of Patients with Marfan will develop cardiac complications.

- Aortic enlargement. This is the most serious potential complication of Marfan syndrome. Because of the abnormalities of the patient's fibrillin, the walls of the aorta (the large blood vessel that carries blood away from the heart) are weaker than normal and tend to stretch and bulge out of shape. This stretching increases the likelihood of an aortic dissection, which is a tear or separation between the layers of tissue that make up the aorta. An aortic dissection usually causes severe pain in the abdomen, back, or chest, depending on the section of the aorta that is affected. Rupture of the aorta is a medical emergency requiring immediate surgery and medication.
- Aortic regurgitation. A weakened and enlarged aorta may allow some blood to leak back into the heart during each heartbeat; this condition is called aortic regurgitation. Aortic regurgitation occasionally causes shortness of breath during normal activity. In serious cases, it causes the left ventricle of the heart to enlarge and may eventually lead to heart failure.
- Mitral valve prolapse. Between 75 and 85% of Marfan patients have loose or "floppy" mitral valves, which are the valves that separate the chambers of the heart. When these valves do not cover the opening between the chambers completely, the condition is called mitral valve prolapse. Complications of mitral valve prolapse include heart murmurs and arrhythmias. In rare cases, mitral valve prolapse can cause sudden death.
- Infective endocarditis. Infective endocarditis is an infection of the endothelium, the tissue that lines the heart. In patients with Marfan, it is the abnormal mitral valve that is most likely to become infected.
- Other complications. Some patients with Marfan develop cystic disease of the lungs or recurrent spontaneous pneumothorax, which is a condition in which air accumulates in the space around the lungs. Many will also eventually develop emphysema.

Musculoskeletal abnormalities

Marfan syndrome causes an increase in the length of the patient's bones, with decreased support from the ligaments that hold the bones together. As a result, the patient may develop various deformities of the skeleton or disorders related to the relative looseness of the ligaments.

Disorders of the spine

- Scoliosis. Scoliosis, or curvature of the spine, is a disorder in which the vertebrae that make up the spine twist out of line from side to side into an S-shape or a spiral. It is caused by a combination of the rapid growth of children with Marfan, and the looseness of the ligaments that help the spine to keep its shape.
- Kyphosis is an abnormal outward curvature of the spine at the back, sometimes called hunch back when it occurs in the upper back. Marfan patients may develop kyphosis either in the upper (thoracic) spine or the lower (lumbar) spine.
- Spondylolisthesis. Spondylolisthesis is the medical term for a forward slippage of one vertebra on the one below it. It produces an ache or stiffness in the lower back.
- Dural ectasia. The dura is the tough, fibrous outermost membrane covering the brain and the spinal cord. The weak dura in Marfan patients swells or bulges under the pressure of the spinal fluid. This swelling is called ectasia. In most cases, dural ectasia occurs in the lower spine, producing low back ache, a burning feeling, or numbness or weakness in the legs.

Disorders of the chest and lower body

- Pectus excavatum. Pectus excavatum is a malformation of the chest in which the patient's breastbone, or sternum, is sunken inward. It can cause difficulties in breathing, especially if the heart, spine, and lung have been affected by Marfan. It also usually causes concerns about appearance.
- Pectus carinatum. In other patients with Marfan the sternum is pushed outward and narrowed. Although pectus carinatum does not cause breathing difficulties, it can cause embarassment about appearance. A few patients with Marfan may have

WWW.BOOKBAZ.IR

a pectus excavatum on one side of their chest and a pectus carinatum on the other.

- Foot disorders. Patients with Marfan are more likely to develop pes planus (flat feet) or so-called "claw" or "hammer" toes than people in the general population. They are also more likely to suffer from chronic pain in their feet.
- Protrusio acetabulae. The acetabulum is the socket of the hip joint. In patients with Marfan, the acetabulum becomes deeper than normal during growth, for reasons that are not yet understood. Although protrusio acetabulae does not cause problems during childhood and adolescence, it can lead to a painful form of arthritis in adult life.

Disorders of the eyes and face

Although the visual problems that are related to Marfan syndrome are rarely life-threatening, they are important in that they may be the patient's first indication of the disorder. Eye disorders related to the syndrome include the following:

- Myopia (nearsightedness). Most patients with Marfan develop nearsightedness, usually in childhood.
- Ectopia lentis. Ectopia lentis is the medical term for dislocation of the lens of the eye. Between 65 and 75% of Marfan patients have dislocated lenses. This condition is an important indication for diagnosis of the syndrome because there are relatively few other disorders that produce it.
- Glaucoma. This condition is much more prevalent in patients with Marfan syndrome than in the general population.
- Cataracts. Patients with Marfan are more likely to develop cataracts, and to develop them much earlier in life, sometimes as early as 40 years of age.
- Retinal detachment. Patients with Marfan are more vulnerable to this disorder because of the weakness of their connective tissues. Untreated retinal detachment can cause blindness. The danger of retinal detachment is an important reason for patients to avoid contact sports or other activities that could cause a blow on the head or being knocked to the ground.
- Other facial problems. Patients with Marfan sometimes develop dental problems related to crowding of the teeth caused by a high-arched palate and a narrow jaw.

Other disorders

- Striae. Striae are stretch marks in the skin caused by rapid weight gain or growth; they frequently occur in pregnant women, for example. Marfan patients often develop striae over the shoulders, hips, and lower back at an early age because of rapid bone growth. Although patients may be self-conscious about the striae, they are not a danger to health.
- Obstructive sleep apnea. Obstructive sleep apnea refers to partial obstruction of the airway during sleep, causing irregular breathing and sometimes snoring. In patients with Marfan, obstructive sleep apnea is caused by the unusual flexibility of the tissues lining the patient's airway. This disturbed breathing pattern increases the risk of aortic dissection.

Diagnosis

There is no objective diagnostic test for Marfan syndrome, in part because the disorder does not produce any measurable biochemical changes in the patient's blood or body fluids, or cellular changes that could be detected from a tissue sample. Although researchers in molecular biology are currently investigating the FBNI gene through a process called mutational analysis, it is presently not useful as a diagnostic test because there is evidence that there can be mutations in the fibrillin gene that do not produce Marfan. Similarly, there is no reliable prenatal test, although some physicians have used **ultrasound** to try to determine the length of fetal limbs in at-risk pregnancies.

The diagnosis is made by taking a family history and a thorough examination of the patient's eyes, heart, and bone structure. The examination should include an echocardiogram taken by a cardiologist, a slit-lamp **eye examination** by an ophthalmologist, and a work-up of the patient's spinal column by an orthopedic specialist. In terms of the cardiac examination, a standard electrocardiogram (EKG) is not sufficient for diagnosis; only the echocardiogram can detect possible enlargement of the aorta. The importance of the slit-lamp examination is that it allows the doctor to detect a dislocated lens, which is a significant indication of the syndrome.

The symptoms of Marfan syndrome in some patients resemble the symptoms of homocystinuria, which is an inherited disorder marked by extremely high levels of homocystine in the patient's blood and urine. This possibility can be excluded by a urine test.

In other cases, the diagnosis remains uncertain because of the mildness of the patient's symptoms, the absence of a family history of the syndrome, and other variables. These borderline conditions are sometimes referred to as marfanoid syndromes.

Treatment

The treatment and management of Marfan is tailored to the specific symptoms of each patient. Some patients find that the syndrome has little impact on their overall lifestyle; others have found their lives centered on the disorder.

Cardiovascular system

After individuals have been diagnosed with Marfan, they should be monitored with an echocardiogram every six months until it is clear that the aorta is not growing larger. After that, they should have an echocardiogram once a year. If the echocardiogram does not allow the physician to visualize all portions of the aorta, CT (computed tomography) or MRI (**magnetic resonance imaging**) may be used. In cases involving a possible **aortic dissection**, the patient may be given a TEE (transesophageal echocardiogram).

Medications. Patients with Marfan may be given drugs called beta-blockers to slow down the rate of aortic enlargement and decrease the risk of dissection by lowering the blood pressure and decreasing the forcefulness of the heartbeat. The most commonly used beta-blockers in Marfan patients are propranolol (Inderal) and atenolol (Tenormin). Patients who are allergic to beta-blockers may be given a **calcium** blocker such as verapamil.

Because these patients are at increased risk for infective **endocarditis**, they must take a prophylactic dose of an antibiotic before having dental work or minor surgery, as these procedures may allow bacteria to enter the bloodstream. Penicillin and amoxicillin are the **antibiotics** most often used.

Surgical treatment. Surgery may be necessary if the width of the patient's aorta increases rapidly or reaches a critical size (about 2 inches). The most common surgical treatment involves replacing the patient's aortic valve and several inches of the aorta itself with a composite graft, which is a prosthetic heart valve sewn into one end of a Dacron tube. This surgery has been performed widely since about 1985; most patients who have had a composite graft have not needed additional surgery.

Patients who have had a valve replaced must take an anticoagulant medication, usually warfarin (Coumadin), in order to minimize the possibility of a clot forming on the prosthetic valve.

Musculoskeletal system

Children diagnosed with Marfan should be checked for **scoliosis** by their pediatricians at each annual **physical examination**. The doctor simply asks the child to bend forward while the back is examined for changes in the curvature. In addition, the child's spine should be x rayed in order to measure the extent of scoliosis or **kyphosis**. The curve is measured in degrees by the angle between the vertebrae as seen on the x ray. Curves of 20° or less are not likely to become worse. Curves between 20 and 40 degrees are likely to increase in children or adolescents. Curves of 40 degrees or more are highly likely to worsen, even in an adult, because the spine is so badly imbalanced that the force of gravity will increase the curvature.

Scoliosis between 20 and 40 degrees in children is usually treated with a back brace. The child must wear this appliance about 23 hours a day until growth is complete. If the spinal curvature increases to 40 or 50 degrees, the patient may require surgery in order to prevent lung problems, back **pain**, and further deformity. Surgical treatment of scoliosis involves straightening the spine with metal rods and fusing the vertebrae in the straightened position.

Spondylolisthesis is treated with a brace in mild cases. If the slippage is more than 30 degree, the slipped vertebra may require surgical realignment.

Dural ectasia can be distinguished from other causes of back pain on an MRI. Mild cases are usually not treated. Medication or spinal shunting to remove some of the spinal fluid are used to treat severe cases.

Pectus excavatum and pectus carinatum can be treated by surgery. In pectus excavatum, the deformed breastbone and ribs are raised and straightened by a metal bar. After four to six months, the bar is removed in an outpatient procedure.

Protrusio acetabulae may require surgery in adult life to provide the patient with an artificial hip joint, if the arthritic pains are severe.

Pain in the feet or limbs is usually treated with a mild analgesic such as **acetaminophen**. Patients with Marfan should consider wearing shoes with low heels, special cushions, or orthotic inserts. Foot surgery is rarely necessary.

Visual and dental concerns

Patients with Marfan should have a thorough eye examination, including a slit-lamp examination, to test for dislocation of the lens as well as nearsightedness. Dislocation can be treated by a combination of special glasses and daily use of one percent atropine sulfate ophthalmic drops, or by surgery.

Because patients with Marfan are at increased risk of **glaucoma**, they should have the fluid pressure

WWW.BOOKBAZ.IR

inside the eye measured every year as part of an eye examination. Glaucoma can be treated with medications or with surgery.

Cataracts are treated with increasing success by implant surgery. It is important, however, to seek treatment at medical centers with eye surgeons familiar with the possible complications of **cataract surgery** in patients with Marfan syndrome.

All persons with Marfan should be taught to recognize the signs of **retinal detachment** (sudden blurring of vision in one eye becoming progressively worse without pain or redness) and to seek professional help immediately.

Children with Marfan should be evaluated by their dentist at each checkup for crowding of the teeth and possible misalignment, and referred to an orthodontist if necessary.

Athletic activities and occupational choice. People with Marfan should avoid sports or occupations that require heavy weight lifting, rough physical contact, or rapid changes in atmospheric pressure (e.g., scuba diving). Weight lifting increases blood pressure, which in turn may enlarge the aorta. Rough physical contact may cause retinal detachment. Sudden changes in air pressure may produce pneumothorax. Regular noncompetitive physical **exercise**, however, is beneficial for Marfan patients. Good choices include brisk walking, shooting baskets, and slow-paced tennis.

Social and lifestyle issues

SMOKING. **Smoking** is particularly harmful for Marfan patients because it increases their risk of **emphysema**.

PREGNANCY. Until very recently, women with Marfan were advised not to become pregnant because of the risk of aortic enlargement or dissection. The development of beta-blockers and echocardiograms, however, allows doctors now to monitor patients throughout **pregnancy**. It is recommended that patients have an echocardiogram during each of the three trimesters of pregnancy. Normal, vaginal delivery is not necessarily more stressful than a Caesarian section, but patients in prolonged labor may be given a Caesarian to reduce strain on the heart. A pregnant woman with Marfan should also receive **genetic counseling** regarding the 50% risk of having a child with the syndrome.

APPEARANCE AND SOCIAL CONCERNS. Children and adolescents with Marfan may benefit from supportive counseling regarding appearance, particularly if their symptoms are severe and causing them to withdraw from social activities. In addition, families may wish to seek counseling regarding the effects of the syndrome on relationships within the family. Many people respond with guilt, fear, or blame when a genetic disorder is diagnosed in the family, or they may overprotect the affected member. Support groups are often good sources of information about Marfan; they can offer helpful suggestions about living with it as well as emotional support.

KEY TERMS

Arachnodactyly—A condition characterized by abnormally long and slender fingers and toes.

Ectopia lentis—Dislocation of the lens of the eye. It is one of the most important single indicators in diagnosing Marfan syndrome.

Fibrillin—A protein that is an important part of the structure of the body's connective tissue. In Marfan's syndrome, the gene responsible for fibrillin has mutated, causing the body to produce a defective protein.

Hypermobility—Unusual flexibility of the joints, allowing them to be bent or moved beyond their normal range of motion.

Kyphosis—An abnormal outward curvature of the spine, with a hump at the upper back.

Pectus carinatum—An abnormality of the chest in which the sternum (breastbone) is pushed outward. It is sometimes called "pigeon breast."

Pectus excavatum—An abnormality of the chest in which the sternum (breastbone) sinks inward; sometimes called "funnel chest."

Scoliosis—An abnormal, side-to-side curvature of the spine.

Prognosis

The prognosis for patients with Marfan has improved markedly in recent years. The life expectancy of people with the syndrome has increased to 72 years, up from 48 years in 1972. This dramatic improvement is attributed to new surgical techniques, improved diagnosis, and new techniques of medical treatment.

The most important single factor in improving the patient's prognosis is early diagnosis. The earlier that a patient can benefit from the new techniques and lifestyle modifications, the more likely he or she is to have a longer life expectancy.

Marijuana

Definition

Marijuana *Cannabis sativa L.*, also known as hemp, is a member of the Cannabaceae family. It contains the psychoactive drug delta-9-tetrahydrocannabinol (THC).

Demographics

The whole cannabis plant, including buds, leaves, seeds, and root, have all been used throughout the long history of this controversial herb. Despite persistent legal restrictions and criminal penalties for illicit use, marijuana continues to be widely used in the United States and throughout the world, both for its mood-altering properties and its medicinal applications. According to the National Survey on drug Use and Health, in 2008, 25.8 million Americans over age 12 had used marijuana within the past year. In 2009, the World Health Organization (WHO) estimated that 147 million people or 2.5% of the world's population used marijuana.

Description

Marijuana is a somewhat weedy plant that can grow as high as 18 ft. (5.4 m). The hairy leaves are arranged opposite one another on the erect and branching stem. Leaves are palmate and compound, deeply divided into five to seven narrow, toothed and pointed leaflets. Male and female flowers are small and greenish in color and grow on separate plants. Male flowers grow in the leaf axils in elongated clusters. The female flowers grow in spike-like clusters. The resinous blossoms have five sepals and five petals. The male and female blossoms can be distinguished at maturity. The male plant matures first, shedding its pollen and dying after flowering. Female plants die after dropping mature seeds.

Marijuana produces an abundance of quickly germinating seeds. This hardy annual is wind pollinated and has escaped from cultivation to grow wild along roadsides, trails, stream banks, and in wayside places throughout the world. The plant matures within three to five months after the seed has been sown.

The species *C. sativa L.* has many variations, depending on the soil, temperature, and light conditions, and the origin of the parent seed. These factors also affect the relative amounts of THC and cannabidiol, the active chemicals present in varying amounts in cannabis, and determine if the plant is primarily a fiber type or an intoxicant. Generally the species grown at higher elevations and in hotter climates exude more of resin and are more potent intoxicants.

History

Marijuana has been cultivated for thousands of years. Cannabis was first described for its therapeutic use in the first known Chinese pharmacopoeia, the *Pen Ts'ao*. (A pharmacopoeia is a book containing a list of medicinal drugs and their descriptions of preparation and use.) Cannabis was called a "superior" herb by the Emperor Shen-Nung (2737-2697 B.C.), who is believed to have authored the work. Cannabis was recommended as a treatment for numerous common ailments.

Around that same period in Egypt, cannabis was used as a treatment for sore eyes. The herb was used in India in cultural and religious ceremonies, and recorded in Sanskrit scriptural texts around 1,400 B.C. Cannabis was considered a holy herb and was characterized as the "soother of grief," "the sky flyer," and "the poor man's heaven."

Centuries later, around 700 B.C., the Assyrian people used the herb they called *Qunnabu,* for incense. The ancient Greeks used cannabis as a remedy to treat inflammation, earache, and **edema**. Shortly after 500 B.C. the historian and geographer Herodotus recorded that the peoples known as Scythians used cannabis to produce fine linens. They called the herb *kannabis* and inhaled the "intoxicating vapor" that resulted when it was burned. By the year 100 B.C. the Chinese were using cannabis to make paper.

Cannabis use and cultivation migrated with the movement of various traders and travelers, and knowledge of the herb's value spread throughout the Middle East, Eastern Europe, and Africa. Around 100, Dioscorides, a surgeon in the Roman Legions

WWW.BOOKBAZ.IR

under the Emperor Nero, named the herb *Cannabis sativa* and recorded numerous medicinal uses. In the second century, the Chinese physician Hoa-Tho, used cannabis in surgical procedures, relying on its analgesic properties. In ancient India, around 600, Sanskrit writers recorded a recipe for "pills of gaiety," a combination of hemp and sugar. By 1150, Muslims were using cannabis fiber in Europe's first paper production. This use of cannabis as a durable and renewable source of paper fiber continued for the next 750 years.

By the 1300s, government and religious authorities, concerned about the psychoactive effects on citizens consuming the herb, began placing harsh restrictions on its use. The Emir Soudon Sheikhouni of Joneima outlawed cannabis use among the poor. He destroyed the crops and ordered that offenders' teeth be pulled out. In 1484, Pope Innocent VIII outlawed the use of hashish, a concentrated form of cannabis. Cannabis cultivation continued, however, because of its economic value as a fiber-producing plant. A little more than a century later, the English queen, Elizabeth I, issued a decree commanding that landowners holding sixty acres or more must grow hemp or pay a fine. Commerce in hemp, which was primarily valued for the strength and versatility of its fibers, was profitable and thriving. Hemp ropes and sails were crossing the sea to North America with the explorers.

By 1621, the British were growing cannabis in Virginia where cultivation of hemp was mandatory. In 1776, the Declaration of Independence was drafted on hemp paper. Both President George Washington and President Thomas Jefferson were advocates of hemp as a valuable cash crop. Jefferson urged farmers to grow the crop in lieu of tobacco. By the 1850s, hemp had become the third largest agricultural crop grown in North America. That year the United States Census recorded 8,327 hemp plantations, each with 2,000 or more acres in cultivation. However, the invention of the cotton gin was already bringing many changes, and cotton was becoming a prime and profitable textile fiber. More change came with the introduction of the sulfite and chlorine processes used to turn trees into paper. Restrictions on the personal use of cannabis as a mood-altering, psychoactive herb, were soon to follow.

Controversy

The 1856 edition of the *Encyclopedia Britannica*, in its lengthy entry on hemp, noted that the herb "produces inebriation and **delirium** of decidedly hilarious character, inducing violent laughter, jumping and dancing." This inebriating effect of marijuana use has fueled the controversy and led to restrictions that have surrounded marijuana use throughout history in many cultures and regions of the world. Cannabis use has been criminalized in some parts of the United States since 1915. Utah was the first state to criminalize it, then California and Texas. By 1923, Louisiana, Nevada, Oregon, and Washington had legal restrictions on the herb. New York prohibited cannabis use in 1927. Despite the restrictions, cannabis use was woven into the cultural and social fabric in some communities, and widespread use persisted, particularly among the Mexican, Asian, and African American populations.

In the United States in 1937, the federal government passed the Marijuana Tax Act, prohibiting the cultivation and farming of marijuana. The act prohibited industrial and medical use of marijuana and classified the flowering tops as a narcotic. Since then, restrictions on the cultivation and use of cannabis have continued. Marijuana was categorized as an illegal narcotic, in the company of **LSD**, heroin, cocaine, and morphine. Despite that, illegal use continued.

In a reversal of the state-by-state progression of criminalizing marijuana that led to the 1937 Marijuana Tax Act, there is a movement underway, state by state, to endorse the legalized use of medical marijuana. By 2010, 14 states in the United States had legalized medical marijuana and two other states had passed laws favorable to its medical use without actually legalizing the drug. A growing body of scientific research and many thousands of years of folk use support the importance of medical marijuana in treatment of a variety of illnesses. The economic value of hemp in the textile, paper, and cordage industries has a long history.

Controversy persists around this herb. The World Health Organization, in a 1998 study, stated that the risks from cannabis use were unlikely to seriously compare to the **public health** risks of the legal drugs, alcohol, and tobacco. Controversy continues on how addictive marijuana is, given the **addiction** potential of many prescription drugs used as **muscle relaxants**, hypnotics, and **analgesics**. One legitimate concern is the effect of **smoking** on the lungs. Cannabis smoke carries even more tars and other particulate matter than tobacco smoke.

Causes and symptoms

Marijuana is ingested by smoking the dried herb, which quickly delivers the active ingredients to the blood system. It can also be added to food (often

KEY TERMS

Antiemetic—A drug or herbal preparation given to relieve nausea and vomiting. Marijuana has antiemetic properties.

Cannabinoids—The chemical compounds that are the active principles in marijuana.

Edema—Swelling of a body tissue due to collection of fluids.

Euphoria—An intense feeling of elation or well being. Many marijuana users experience temporary euphoria.

Glaucoma—An eye disorder caused by damage to the optic nerve resulting in vision loss. Glaucoma is usually accompanied by inflammation and increased pressure in the eye (intraocular pressure). There are several types that may develop suddenly or gradually.

brownies) and eaten. Cannabis contains chemical compounds known as cannabinoids. Different cannabinoids seem to exert different effects on the body after ingestion. Scientific research indicates that these substances have potential therapeutic value for **pain** relief, control of **nausea and vomiting**, and appetite stimulation. The primary active agent is THC. This chemical may constitute as much as 12% of the active chemicals in the herb, and is said to be responsible for as much as 70–100% of the euphoric response, or "high," experienced when ingesting the herb. The predominance of this mental lightness or euphoria depends on the balance of other active ingredients and the freshness of the herb. THC degrades into a component known as cannabinol, or CBN. This relatively inactive chemical predominates in marijuana that has been stored too long before use. Another chemical component, cannabidiol, known as CBD, has a sedative and mildly analgesic (pain relieving) effect, and contributes to lethargy sometimes experienced by marijuana users.

Despite the fact that on the federal level marijuana use remains illegal, in the United States in the twenty-first century there is strong interest in medicinal uses of marijuana. The herb appears to have analgesic, antiemetic, anti-inflammatory, sedative, anticonvulsive, and laxative actions. Clinical studies have demonstrated its effectiveness in relieving nausea and **vomiting** following **chemotherapy** treatments for cancer. The herb has also been shown to reduce intra-ocular pressure in the eye a beneficial action in the treatment for **glaucoma**. However, marijuana is not more effective in lowering pressure in the eye than legal prescription drugs.

Cannabis has proven anticonvulsive action, and may be helpful in treating **epilepsy**. Marijuana also increases appetite and reduces nausea and has been used with **AIDS** patients to counter weight loss and wasting that may result from the disease. Several chemical constituents of cannabis displayed antimicrobial action and antibacterial effects in research studies. The components CBC and THC have been shown to destroy and inhibit the growth of streptococci and staphylococci bacteria. In 2007, a Harvard University study found that the active ingredient of marijuana cut lung tumor growth in mice in half.

Because marijuana use is illegal in many places and because of the conditions under which the plants are raised causes variation in the amounts of active ingredients, there is no standard dosage for medical use. In states that have legalized the use of medical marijuana, the legally permissible amounts for an individual to possess range from 1 oz. (28 g) to 24 oz. (680 g). THC extract is available legally in some countries in capsule form. In the United States this form of THC is available only for clinical experimental purposes.

The *PDR for Herbal Medicine* reports that the most common effect of marijuana use is psychotropic, as a euphoric state (pronounced gaiety, laughing fits) occurs almost immediately after smoking the herb. Long-term usage leads to a clear increase in tolerance for most of the pharmacological effects. Chronic use results in increased risk of **laryngitis**, **bronchitis**, apathy, psychic decline, and disturbances of sexual functions. In addition chronic sinus and **fungal infections** have been linked to chronic marijuana smoking.

Research has shown that cannabis acts to increase heartbeat by as much as 40 beats per minute. A study reported by the American Heart Association concluded that smoking marijuana can precipitate a **heart attack** in persons with pre-existing heart conditions. One hour after smoking marijuana, the likelihood of having a heart attack is 4.5 times greater than if the person had not smoked, according to the research. Marijuana also can cause a drop in blood pressure resulting in **dizziness**.

Marijuana use during **pregnancy** has been found to reduce the newborn's birth weight, a possible indication of problems. Pregnant and **breastfeeding** women should avoid using marijuana. Other research has shown that marijuana decreases male fertility and increases the number of abnormal sperm found in semen.

WWW.BOOKBAZ.IR

An additional health concern is the effect that marijuana smoking has on the lungs. Cannabis smoke carries more tars and other particulate matter than tobacco smoke. Long-term use is also associated with an increase in respiratory diseases such as bronchitis.

Studies have shown that motor coordination and driving ability can be impaired for up to eight hours after smoking marijuana. Individuals should avoid driving and using heavy machinery for several hours after using the herb.

More seriously, marijuana has been linked to the onset or worsening of certain psychiatric conditions, including **panic disorder**, **schizophrenia**, and depersonalization disorder. Persons diagnosed with or at risk for these conditions should not use marijuana. Chronic marijuana use also interferes with the ability to organize and recall complex information.

Marijuana use may mask the perceived effects of alcohol and cocaine when the drugs are consumed together. Marijuana is said to exert a synergistic effect with other medicinal agents. When used with nitrous oxide it may enhance the nitrous oxide effect.

Marijuana use by individuals taking selective serotonin re-uptake inhibitors (SSRIs, used to treat depression) may develop manic symptoms. Use in individuals taking tricyclic antidepressants can produce delirium and racing heart (tachycardia).

In the United States, marijuana is considered a Class I narcotic, and federal law has restricted its use since 1937. Penalties include fines and imprisonment in some states, but the herb has been decriminalized in others. California, for example, issues cards identifying medical marijuana users and allows them to purchase the drug openly at certain clinics. As of late 2014, 23 states along with the District of Columbia, had enacted laws that legalized medical marijuana. One states had pending legislation or ballot measures to legalize medical marijuana (Ohio) In other countries, the legal status of and penalty for using marijuana vary widely.

Illegally purchased marijuana carries the potential to be laced with other toxins and mind-altering drugs. Since marijuana is illegal under federal law, there are no regulations or quality control to establish standardized purity of the herb.

Diagnosis

Marijuana use can be diagnosed through a urine drug-screening test. The drug is definitely detectable in urine for 1–5 days after use; however, it may be detected in the urine for as long as 21 days after use. Marijuana use is commonly looked for in pre-employment drug screening.

Treatment

Many people do not consider recreational marijuana use harmful, especially as the medical community is increasingly recognizing that the drug has medically beneficial qualities. Marijuana use often occurs in conjunction with abuse of alcohol and other drugs. In this situation, treatment of the other drug often takes precedence over treatment for marijuana use. **Cognitive-behavioral therapy**, in which users learn to recognize, manage and avoid situations most likely to lead to marijuana use and develop healthy ways to cope with stressful situations can be successful in stopping marijuana use in motivated individuals.

Prognosis

Marijuana use peaks during adolescence and then gradually declines, although there are still many older adults who use marijuana recreationally. Although marijuana is less likely than some other drugs to lead to dependence, heavy users may experience a withdrawal syndrome characterized by **anxiety**, irritability, chills, and **muscle cramps** if they stop usage abruptly.

Prevention

Recreational marijuana use is difficult to prevent, and drug education programs have not been successful in reducing the number of people who experiment with marijuana. As medical use of marijuana becomes more common, attitudes in the United States have shifted away from punishing individuals who possess small amounts of marijuana for personal use, making prevention increasingly difficult.

Marriage counseling

Definition

Marriage counseling is a type of **psychotherapy** for a married couple or established partners that tries to resolve problems in the relationship. Typically, two people attend counseling sessions together to discuss specific issues; however, in some cases only one partner works within the sessions. It may also be called marital therapy, couples therapy, or relationship counseling.

Before the late twentieth century, close friends, family members, or religious leaders primarily performed marriage counseling. Since then, the guidance most often comes from psychiatrists, psychologists, social workers, and marriage/family counselors. With the use of such professionals, certifications and regulations have been established to guide and control these activities. One of the most commonly accepted credentials comes from the American Association for Marriage and **Family Therapy**.

Purpose

Marriage counseling provides help to couples, whether they are married or not, and whether the pair are heterosexual or homosexual. It is based on research showing that individuals and their problems are best handled within the context of their relationships. Marriage counselors are trained in psychotherapy and family systems, and focus on understanding their clients' symptoms and the way their interactions contribute to problems in the relationship.

Various issues are discussed in marriage counseling. Some of the more critical issues addressed include:

- Infidelity issues
- Sexual problems
- Financial difficulties
- Physical disabilities
- Mental illnesses
- Anger management problems
- Domestic abuse
- Alcohol/substance abuse
- Communications difficulties
- Children and other family members interactions

Description

Marriage counseling is usually a short-term therapy that may take only a few sessions to work out problems in the relationship. Longer-term counseling

WWW.BOOKBAZ.IR

may also occur, with a range of sessions usually from 12 to 24. Typically, marriage counselors ask questions about the couple's roles, patterns, rules, goals, and beliefs. Therapy often begins as the couple analyzes the good and bad aspects of the relationship. The marriage counselor then works with the couple to help them understand that, in most cases, both partners are contributing to problems in the relationship. When this is understood, the two can then learn to change how they interact with each other to solve problems. The partners may be encouraged to draw up a contract in which each partner describes the behavior that partner will be trying to maintain. Sometimes counseling is also provided for the entire family, not just for a couple.

Marriage is not a requirement for two people to get help from a marriage counselor. Any single person wishing to improve his or her relationships can acquire help with behavioral problems, relationship issues, or with mental or emotional disorders. Marriage counselors also offer treatment (pre-marital therapy) for couples before they get married to help them understand potential problem areas. A third type of marriage counseling involves post-marital therapy, in which divorcing couples who share children seek help in working out their differences. Couples in the midst of a divorce find that marriage therapy during separation can help them find a common ground as they negotiate interpersonal issues and child custody.

Choosing a therapist

A marriage counselor is trained to use different types of therapy in work with individuals, couples, and groups. American Association of Marriage and Family Therapy (AAMFT) training includes supervision by experienced therapists, who hold a minimum of a master's degree (including specific training in marriage and family therapy), and specific graduate training in marriage and family therapy.

When looking for a marriage counselor, a couple should find out the counselor's training and educational background, professional associations, such as the AAMFT, and state licensure, and whether the person has experience in treating particular kinds of problem. Also, questions should be asked concerning fees, insurance coverage, the average length of therapy, and so on.

Results

Marriage counseling helps couples learn to deal more effectively with problems, and can help prevent small problems from becoming serious. Research shows that marriage counseling, when effective, tends to improve a person's physical as well as mental health, in addition to improving the relationship.

Marshall-Marchetti-Krantz procedure

Definition

The Marshall-Marchetti-Krantz procedure surgically reinforces the bladder neck in order to prevent unintentional urine loss.

Purpose

The Marshall-Marchetti-Krantz procedure is performed to correct **stress** incontinence in women, a common result of **childbirth** and/or **menopause**. Incontinence also occurs when an individual involuntarily loses urine after pressure is placed on the abdomen (like during **exercise**, sexual activity, sneezing, coughing, laughing, or hugging).

Precautions

In some women, stress incontinence may be controlled through nonsurgical means, such as:

- Kegel exercises (exercises that tighten pelvic muscles)
- Biofeedback (monitors temperature and muscle contractions in the vagina to help incontinent patients control their pelvic muscles)
- Bladder training (behavioral modification program used to treat stress incontinence)
- Medication
- Inserted incontinence devices

Each patient should undergo a full diagnostic workup to determine the best course of treatment.

Description

The Marshall-Marchetti-Krantz procedure, also known as **retropubic suspension** or bladder neck suspension surgery, is performed by a surgeon in a hospital setting. The patient is placed under general **anesthesia**, and a long, thin, flexible tube (catheter) is inserted into the bladder through the narrow tube (urethra) that drains the body's urine. An incision is made across the abdomen, and the bladder is exposed. The bladder is separated from surrounding tissues. Stitches (sutures) are placed in these tissues near the bladder neck and urethra. The urethra is then lifted, and the sutures are attached to the pubic bone itself, or to tissue (fascia) behind the pubic bone. The sutures support the bladder neck, helping the patient gain control over urine flow.

Preparation

A complete evaluation to determine the cause of incontinence is critical to proper treatment. A thorough medical history and general **physical examination** should be performed on candidates for the Marshall-Marchetti-Krantz procedure. Diagnostic testing may include x rays, **ultrasound**, urine tests, and examination of the pelvis. It may also include a series of urodynamic testing exams that measure bladder pressure and capacity, and urinary flow.

Patients undergoing a Marshall-Marchetti-Krantz procedure must not eat or drink for eight hours prior to the surgery.

Aftercare

Recovery from a Marshall-Marchetti-Krantz procedure requires two to six days of hospitalization. The catheter will be removed from the patient's bladder once normal bladder function resumes. Patients are advised to refrain from heavy lifting for four to six weeks after the procedure.

Patients should contact their physician immediately if they experience **fever**, **dizziness**, or extreme nausea, or if their incision site becomes swollen, red, or hard.

KEY TERMS

Biofeedback—Biofeedback training monitors temperature and muscle contractions in the vagina to help incontinent patients control their pelvic muscles.

Bladder training—A behavioral modification program used to treat stress incontinence. Bladder training involves putting the patient on a toilet schedule, and gradually increasing the time interval between urination.

Catheter—A long, thin, flexible tube. A catheter is used to drain the bladder of urine during a Marshall-Marchetti-Krantz procedure.

Kegel exercises—Exercises that tighten the pelvic floor muscles. Kegel exercises can assist some women in controlling their stress incontinence.

Urethra—The narrow tube, leading from the bladder that drains the body's urine.

Risks

The Marshall-Marchetti-Krantz procedure is an invasive surgical procedure, and, as such, it carries risks of infection, internal bleeding, and hemorrhage. There is also a possibility of permanent damage to the bladder or urethra. The urethra may become scarred, causing a permanent narrowing, or stricture.

Results

Approximately 85% of women who undergo the Marshall-Marchetti-Krantz procedure are cured of their stress incontinence.

Massage therapy

Definition

Massage therapy is the scientific manipulation of the soft tissues of the body for the purpose of normalizing those tissues and consists of manual techniques that include applying fixed or movable pressure, holding, and/or causing movement of or to the body.

Purpose

Generally, massage is known to affect the circulation of blood and the flow of blood and lymph, reduce muscular tension or flaccidity, affect the nervous system through stimulation or **sedation**, and enhance tissue healing. These effects provide a number of benefits:

- reduction of muscle tension and stiffness
- relief of muscle spasms
- greater flexibility and range of motion
- increase of the ease and efficiency of movement
- relief of stress and aide of relaxation
- promotion of deeper and easier breathing
- improvement of the circulation of blood and movement of lymph
- relief of tension-related conditions, such as headaches and eyestrain
- promotion of faster healing of soft tissue injuries, such as pulled muscles and sprained ligaments, and reduction in pain and swelling related to such injuries
- reduction in the formation of excessive scar tissue following soft tissue injuries
- enhancement in the health and nourishment of skin
- improvement in posture through changing tension patterns that affect posture
- reduction in stress and an excellent stress management tool
- creation of a feeling of well-being
- reduction in levels of anxiety
- increase in awareness of the mind-body connection
- promotion of a relaxed state of mental awareness

Massage therapy also has a number of documented clinical benefits. For example, massage can reduce **anxiety**, improve pulmonary function in young people with asthma, reduce psycho-emotional distress in persons suffering from chronic inflammatory bowel disease, increase weight and improve motor development in premature infants, and may enhance immune system functioning. Some medical conditions that massage therapy can help are: **allergies**, anxiety and **stress**, arthritis, asthma and **bronchitis**, **carpal tunnel syndrome** and other repetitive motion injuries, chronic and temporary **pain**, circulatory problems, depression, digestive disorders, **tension headache**, **insomnia**, myofascial pain, **sports injuries**, and temporomandibular joint dysfunction.

Description

Origins

Massage therapy is one of the oldest healthcare practices known to history. References to massage are found in Chinese medical texts more than 4,000 years old. Massage has been advocated in Western healthcare practices at least since the time of Hippocrates, the "Father of Medicine." In the fourth century B.C. Hippocrates wrote, "The physician must be acquainted with many things and assuredly with rubbing" (the ancient Greek term for massage was rubbing).

The roots of modern, scientific massage therapy go back to Per Henrik Ling (1776–1839), a Swede, who developed an integrated system consisting of massage and active and passive exercises. Ling established the Royal Central Gymnastic Institute in Sweden in 1813 to teach his methods.

Modern, scientific massage therapy was introduced in the United States in the 1850s by two New York physicians, brothers George and Charles Taylor, who had studied in Sweden. The first clinics for massage therapy in the United States were opened by two Swedish physicians after the Civil War period. Doctor Baron Nils Posse operated the Posse Institute in Boston and Hartwig Nissen opened the Swedish Health Institute near the Capitol in Washington, D.C.

Although there were periods when massage fell out of favor, in the 1960s it made a comeback in a different way as a tool for relaxation, communication, and alternative healing. Today, massage is one of the most popular healing modalities. It is used by conventional, as well as alternative, medical communities and is now covered by some health insurance plans.

Massage therapy is the scientific manipulation of the soft tissues of the body for the purpose of normalizing those tissues and consists of a group of manual techniques that include applying fixed or movable pressure, holding, and/or causing movement of or to the body. While massage therapy is applied primarily with the hands, sometimes the forearms or elbows are used. These techniques affect the muscular, skeletal, circulatory, lymphatic, nervous, and other systems of the body. The basic philosophy of massage therapy embraces the concept of *vis Medicatrix naturae*, which

is aiding the ability of the body to heal itself and is aimed at achieving or increasing health and well-being.

Touch is the fundamental medium of massage therapy. While massage can be described in terms of the type of techniques performed, touch is not used solely in a mechanistic way in massage therapy. One could look at a diagram or photo of a massage technique that depicts where to place one's hands and what direction the **stroke** should go, but this would not convey everything that is important for giving a good massage. Massage also has an artistic component.

Because massage usually involves applying touch with some degree of pressure and movement, the massage therapist must use touch with sensitivity in order to determine the optimal amount of pressure to use for each person. For example, using too much pressure may cause the body to tense up, while using too little may not have enough effect. Touch used with sensitivity also allows the massage therapist to receive useful information via his or her hands about the client's body, such as locating areas of muscle tension and other soft tissue problems. Because touch is also a form of communication, sensitive touch can convey a sense of caring—an essential element in the therapeutic relationship—to the person receiving massage.

In practice, many massage therapists use more than one technique or method in their work and sometimes combine several. Effective massage therapists ascertain each person's needs and then use the techniques that will meet those needs best.

Swedish massage uses a system of long gliding strokes, kneading, and friction techniques on the more superficial layers of muscles, generally in the direction of blood flow toward the heart, and sometimes combined with active and passive movements of the joints. It is used to promote general relaxation, improve circulation and range of motion, and relieve muscle tension. Swedish massage is the most commonly used form of massage.

Deep tissue massage is used to release chronic patterns of muscular tension using slow strokes, direct pressure, or friction directed across the grain of the muscles. It is applied with greater pressure and to deeper layers of muscle than Swedish, which is why it is called deep tissue and is effective for chronic muscular tension.

Sports massage uses techniques that are similar to Swedish and deep tissue, but are specially adapted to deal with the effects of athletic performance on the body and the needs of athletes regarding training, performing, and recovery from injury.

Neuromuscular massage is a form of deep massage that is applied to individual muscles. It is used primarily to release trigger points (intense knots of muscle tension that refer pain to other parts of the body), and also to increase blood flow. It is often used to reduce pain. Trigger point massage and myotherapy are similar forms.

Acupressure applies finger or thumb pressure to specific points located on the **acupuncture** meridians (channels of energy flow identified in Asian concepts of anatomy) in order to release blocked energy along these meridians that causes physical discomforts, and rebalance the energy flow. **Shiatsu** is a Japanese form of acupressure.

The cost of massage therapy varies according to geographic location, experience of the massage therapist, and length of the massage. In the United States, the average range is from $35-60 for a one hour session. Massage therapy sessions at a client's home or office may cost more due to travel time for the massage therapist. Most sessions are one hour. Frequency of massage sessions can vary widely. If a person is receiving massage for a specific problem, frequency can vary widely based on the condition, though it usually will be once a week. Some people incorporate massage into their regular personal health and fitness program. They will go for massage on a regular basis, varying from once a week to once a month.

The first appointment generally begins with information gathering, such as the reason for getting massage therapy, physical condition and medical history, and other areas. The client is asked to remove clothing to one's level of comfort. Undressing takes place in private, and a sheet or towel is provided for draping. The massage therapist will undrape only the part of the body being massaged. The client's modesty is respected at all times. The massage therapist may use an oil or cream, which will be absorbed into the skin in a short time.

To receive the most benefit from a massage, generally the person being massaged should give the therapist accurate health information, report discomfort of any kind (whether it is from the massage itself or due to the room temperature or any other distractions), and be as receptive and open to the process as possible.

Insurance coverage for massage therapy varies widely. There tends to be greater coverage in states that license massage therapy. In most cases, a physician's prescription for massage therapy is needed. Once massage therapy is prescribed, authorization

WWW.BOOKBAZ.IR

from the insurer may be needed if coverage is not clearly spelled out in one's policy or plan.

Preparations

Going for a massage requires little in the way of preparation. Generally, one should be clean and should not eat just before a massage. One should not be under the influence of alcohol or non medicinal drugs. Massage therapists generally work by appointment and usually will provide information about how to prepare for an appointment at the time of making the appointment.

Precautions

Massage is comparatively safe; however it generally should not be used if a person has one of the following conditions: advanced heart diseases **hypertension** (high blood pressure), phlebitis, thrombosis, **embolism**, kidney failure, cancer if massage would accelerate metastasis (i.e., spread a tumor) or damage tissue that is fragile due to **chemotherapy** or other treatment, infectious diseases, contagious skin conditions, acute inflammation, infected injuries, unhealed **fractures**, **dislocations**, frostbite, large hernias, torn ligaments, conditions prone to hemorrhage, and **psychosis**.

Massage should not be used locally on affected areas for the following conditions: **rheumatoid arthritis** flare up, **eczema**, **goiter**, and open **skin lesions**. Massage may be used on the areas of the body that are not affected by these conditions.

In some cases, precautions should be taken before using massage for the following conditions: **pregnancy**, high fevers, **osteoporosis**, diabetes, recent postoperative cases in which pain and muscular splinting (i.e., tightening as a protective reaction) would be increased, apprehension, and mental conditions that may impair communication or perception. In such cases, massage may or may not be appropriate. The decision on whether to use massage must be based on whether it may cause harm. For example, if someone has osteoporosis, the concern is whether bones are strong enough to withstand the pressure applied. If one has a health condition and has any hesitation about whether massage therapy would be appropriate, a physician should be consulted.

Side effects

Massage therapy does not have side effects. Sometimes people are concerned that massage may leave them too relaxed or too mentally unfocused. To the contrary, massage tends to leave people feeling more relaxed and alert.

Research and general acceptance

Before 1939, more than 600 research studies on massage appeared in the main journals of medicine in English. However, the pace of research was slowed by medicine's disinterest in massage therapy.

Massage therapy research picked up again in the 1980s, as the growing popularity of massage paralleled the growing interest in complementary and alternative medicine. Well designed studies have documented the benefits of massage therapy for the treatment of acute and chronic pain, acute and chronic inflammation, chronic **lymphedema**, nausea, muscle spasm, various soft tissue dysfunctions, anxiety, depression, insomnia, and psycho-emotional stress, which may aggravate mental illness.

Premature infants treated with daily massage therapy gain more weight and have shorter hospital stays than infants who are not massaged. A study of 40 low-birth-weight babies found that the 20 massaged babies had a 47% greater weight gain per day and stayed in the hospital an average of six days less than 20 infants who did not receive massage, resulting a cost savings of approximately $3,000 per infant. Cocaine-exposed, preterm infants given massage three times daily for a 10-day period showed significant improvement. Results indicated that massaged infants had fewer postnatal complications and exhibited fewer stress behaviors during the 10 day period, had a 28% greater daily weight gain, and demonstrated more mature motor behaviors.

A study comparing 52 hospitalized depressed and adjustment disorder children and adolescents with a control group that viewed relaxation videotapes, found massage therapy subjects were less depressed and anxious and had lower saliva cortisol levels (an indicator of less depression).

Another study showed massage therapy produced relaxation in 18 elderly subjects, demonstrated in measures such as decreased blood pressure and heart rate and increased skin temperature.

A combination of massage techniques for 52 subjects with traumatically induced spinal pain led to significant improvements in acute and chronic pain and increased muscle flexibility and tone. This study also found massage therapy to be extremely cost effective, with cost savings ranging from 15-50%. Massage has also been shown to stimulate the body's ability to naturally control pain by stimulating the brain to

produce endorphins. **Fibromyalgia** is an example of a condition that may be favorably affected by this effect.

A pilot study of five subjects with symptoms of tension and anxiety found a significant response to massage therapy in one or more psycho-physiological parameters of heart rate, frontalis and forearm extensor electromyograms (EMGs) and skin resistance, which demonstrate relaxation of muscle tension and reduced anxiety.

Lymph drainage massage has been shown to be more effective than mechanized methods or diuretic drugs to control lymphedema secondary to radical **mastectomy**, consequently using massage to control lymphedema would significantly lower treatment costs. A study found that massage therapy can have a powerful effect upon psycho-emotional distress in persons suffering from chronic inflammatory bowel disease. Massage therapy was effective in reducing the frequency of episodes of pain and disability in these patients.

Massage may enhance the immune system. A study suggests an increase in cytotoxic capacity associated with massage. A study of **chronic fatigue syndrome** subjects found that a group receiving massage therapy had lower depression, emotional distress, and somatic symptom scores, more hours of sleep, and lower epinephrine and cortisol levels than a control group.

Mastectomy

Definition

Mastectomy is the surgical removal of part or all of a breast—and sometimes additional tissue—for the treatment or prevention of **breast cancer**.

Purpose

More than 100,000 mastectomies are performed each year in the United States. Although the vast majority are performed to treat breast cancer, an increasing number of women are choosing prophylactic mastectomy.

Cancer treatment

Breast cancer is treated with mastectomy when one or more of the following is the case:

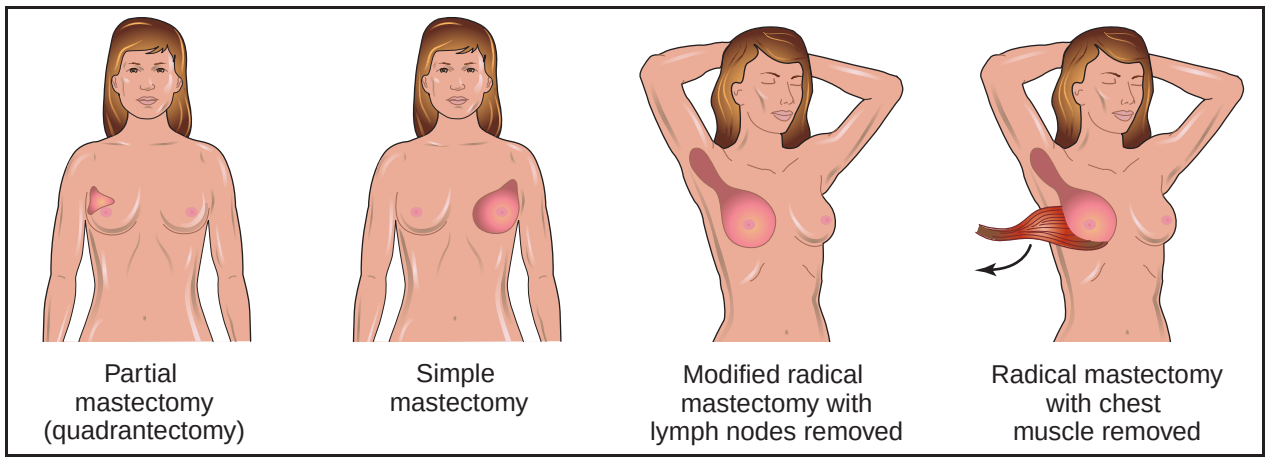
- The cancer is advanced, and all of the breast tissue and possibly lymph nodes and muscles must be removed.
- The tumor is large and would be difficult to remove with good cosmetic results by breast-conserving surgery.
- The breast is small or shaped such that breast-conserving surgery would leave very little tissue.
- A sufficient amount of normal tissue surrounding the tumor—the margin of resection—cannot be removed along with the tumor.
- Radiation therapy following breast-conserving surgery is not appropriate or possible.

Many women with earlier-stage breast cancers choose to have a full mastectomy rather than a breast-conserving **lumpectomy** or segmental mastectomy, even though the latter are just as effective and survival rates are just as high as with a mastectomy. A 2013 study found that a majority of women under 40 opted for mastectomies rather than a more modest surgical procedure followed by radiation treatments. Some women fear radiation or are unable to undergo **radiation therapy** because of **pregnancy**, an underlying medical condition, or because of the time commitment, travel distance, or cost. Some women choose a mastectomy because they want **breast reconstruction** surgery. Other women are afraid that their cancer will recur and achieve greater peace of mind with a mastectomy. However, women in the United States are more likely to have mastectomies than women in other countries, and there is growing concern over the increase in unnecessary mastectomies.

Prophylactic mastectomy

Prophylactic or preventive mastectomy—removal of one or both breasts to prevent possible future breast cancer—is controversial. The rate of prophylactic mastectomies increased by an estimated 50% in the early 2000s. Some researchers worry that prophylactic mastectomies are reaching almost epidemic proportions with little medical justification. Fear generated by breast-cancer awareness campaigns, improvements in breast **reconstructive surgery**, and celebrity disclosures of prophylactic mastectomies all may be contributing to this trend. Nevertheless, undergoing a prophylactic mastectomy is no guarantee that breast cancer will not develop or recur.

WWW.BOOKBAZ.IR



There are four types of mastectomies: partial mastectomy, or lumpectomy, in which the tumor and surrounding tissue is removed; simple mastectomy, where the entire breast and some axillary lymph nodes are removed; modified radical mastectomy, in which the *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

About 5%–10% of breast cancers result from specific mutations in the breast cancer susceptibility genes BRCA1 and BRCA2. Women with these mutations have a very high likelihood of developing breast cancer, and the younger they are when the cancer develops, the more aggressive the disease. Many women with BRCA mutations choose to have prophylactic double (bilateral) mastectomies.

An increasing number of women are choosing double mastectomies after developing cancer in one breast, even though the risk of cancer in the healthy breast is only about 1% per year. By 2013, up to 15% of women with breast cancer were choosing double mastectomies, compared with less than 3% in the late 1990s. Studies have suggested that 70% of these double mastectomies may be unnecessary.

Bilateral prophylactic mastectomy is sometimes performed on high-risk women with lobular carcinoma-in-situ (LCIS), in which abnormal cells are found in the milk-producing glands. Although LCIS seldom becomes invasive, it increases the risk of breast cancer in either breast. While most surgeons consider prophylactic mastectomy for LCIS to be unnecessary, the number of such surgeries increased by 50% between 2000 and 2013.

Description

Mastectomies are typically performed under general **anesthesia** in a hospital and require at least an overnight stay. Immediate breast reconstruction requires a longer hospital stay. However, an increasing number of mastectomies are performed in specialized outpatient facilities. A mastectomy with lymph node dissection—the removal of axillary (underarm) lymph nodes—takes 90–120 minutes.

An oval-shaped incision is usually made around the nipple across the width of the breast. The type and location of the incision may vary according to breast reconstruction plans or other factors. The diseased and at-risk tissue is removed and sent to a pathology laboratory for analysis. If no immediate breast reconstruction is planned, surgical drains are left in place to prevent fluid accumulation. The skin is sutured and bandages or dressings are applied. The stitches later dissolve or surgical staples are removed at an office visit.

Types of mastectomies

With a total or **simple mastectomy**, the breast tissue is separated from the overlying skin and the underlying chest wall muscle. All the breast tissue—from the collarbone to the ribs and from the side of the body to the breastbone—is removed. One or more axillary lymph nodes may be removed through a separate incision to be checked for cancerous cells.

A **modified radical mastectomy** is the most common type. It removes the breast, nipple, an ellipse of skin, most of the underarm lymph nodes, and often the lining over the chest muscles, but usually leaves the chest muscles intact. The surgery leaves the woman with a more normal chest shape than a radical mastectomy and a less visible scar. It also allows for immediate or delayed breast reconstruction.

A radical or Halsted mastectomy removes the breast, all surrounding lymph nodes up to the collarbone, and the chest muscle. The procedure was

developed in the late 1800s, when it was believed that extensive surgery was more likely to cure cancer. Radical mastectomies often left women disfigured and disabled, with a large defect in the chest wall requiring **skin grafting** and with significantly decreased sensation and motion in the arm. Radical mastectomies are now performed only for recurrent breast cancer or when the tumor has spread to the chest muscle.

Breast-conserving surgeries include lumpectomies, in which only the tumor and a small amount of surrounding normal tissue are removed, and partial or segmental mastectomies, in which the cancerous region, surrounding normal tissue, and possibly the lining over the chest muscles below the cancer are removed. Lymph node dissection may be performed at the same time, or later through a separate incision.

Skin-sparing mastectomy and breast reconstruction

If a woman is not going to have immediate breast reconstruction, the surgeon removes as much of the breast skin as is necessary to flatten the surface of the chest and scar. In contrast, a skin-sparing mastectomy removes the breast tissue through a small incision, leaving the breast skin to accommodate a soft-tissue reconstruction or breast implant. The nipple and areola may also be removed, although some studies have found little difference in recurrence rates after nipple-sparing mastectomy.

Breast reconstruction surgery may be performed at the time of the mastectomy or months or even years later, depending on the site and type of cancer and the woman's overall health. The reconstructive surgery is performed by a plastic surgeon. Mastectomy with reconstruction surgery can take up to five or six hours. Tissue-flap surgery reconstructs the breast with the patient's own muscle, fat, and skin taken from other parts of the body. Alternatively, reconstruction may use implants filled with saline or silicone gel. Surgery is sometimes performed on the other breast so that both breasts are approximately the same size and shape. A drain may be placed in the armpit after the surgery, which usually requires a hospital stay of three days or less. Insurance companies are required to cover breast reconstructions in conjunction with mastectomies.

Some women prefer not to have reconstructive surgery. Tissue flap is major surgery and may not be appropriate for women who are very thin or obese, who smoke, or who have other health conditions.

Precautions

A choice between a mastectomy and breast-conserving surgery should be considered carefully. Mastectomy results in a significant loss of sensation in the breast, which may affect self-image or sexual feelings. Furthermore, although studies have found that women who choose preventive mastectomy are generally satisfied with their choice, the women also report that they had inadequate prior information about the surgery, **genetic testing**, and breast reconstruction.

Preparation

Surgical treatment for breast cancer is often performed within a few weeks of diagnosis. Sometimes **chemotherapy** is used before surgery to shrink the tumor and reduce the amount of tissue that must be surgically removed. One study found that treatment with aromatase inhibitors, such as anastrozole, can shrink large, endocrine-rich tumors in postmenopausal women, allowing many of them to have breast-conserving surgery instead of a mastectomy.

Routine preoperative preparations, such as not eating or drinking the night before surgery, are typically required. The patient may be asked to donate blood in case a blood **transfusion** is necessary. Women should stop taking **aspirin**, **nonsteroidal anti-inflammatory drugs** such as ibuprofen, and possibly other medications several weeks before surgery.

Aftercare

Many mastectomy patients go home the same day or within a day or two. However, they may need to change bandages and/or care for the incision. Surgical drains must be properly attended to, including measuring and emptying the fluid. If a drain becomes blocked, fluid or blood may collect at the surgical site, which can cause infection and/or delay wound healing. **Pain** is usually controlled with prescribed medication. Severe pain may be a sign of complications. A return visit to the surgeon is usually scheduled seven to ten days after the procedure. Activities such as driving may be restricted.

Physical therapy is an integral part of mastectomy aftercare. Exercises to maintain shoulder and arm mobility may be prescribed as early as 24 hours after surgery. However, intense **exercise** should be avoided for a time. The affected area must be protected from infection, pressure, constriction, or injury, especially if axillary lymph nodes were removed.

WWW.BOOKBAZ.IR

Emotional care is an important aspect of recovery from a mastectomy. Women may experience anger, depression, negative self-image, and grief, as well as **anxiety** over possible cancer recurrence. Assistance in dealing with the psychological effects of a breast cancer diagnosis, as well as the surgery, can be invaluable.

Following a lumpectomy or mastectomy, a pathologist examines the removed tissue to confirm that the margins of resection are free of cancer cells. This ensures that all of the cancer has been removed. The size of the margins—the distance between the tumor and the edges of the tissue—helps determine the need for additional treatment. If cancer cells extend out to the edge, additional surgery called re-excision will be performed. Other breast cancer treatments following mastectomy may include chemotherapy, radiation therapy, hormone therapy, and/or targeted therapy. Radiation therapy almost always follows breast-conserving surgery.

Risks

Mastectomy risks include:

- risks associated with general anesthesia
- excessive bleeding during or after surgery, particularly with a double mastectomy or breast reconstruction
- numbness at the incision site and mild-to-moderate tenderness adjacent to the site due to severed nerves
- delayed wound healing from fluid or blood accumulation
- infection
- unexpected scarring
- phantom breast symptoms, such as itching or aching in a breast that has been removed
- scarring from lymph node removal, resulting in decreased arm mobility and requiring more intense physical therapy
- complications arising from breast reconstruction surgery

Approximately 10%–20% of patients develop **lymphedema** after axillary lymph node removal. This complication can arise at any time, even years after surgery. This mild-to-severe swelling of the arm caused by faulty lymph drainage is a chronic condition that requires continuing treatment. Severe cases can be disabling. A type of biopsy known as sentinel lymph node mapping and biopsy often eliminates the need to remove lymph nodes.

Results

Women are usually cancer free following a mastectomy. For a single tumor of less than 1.6 in. (4 cm) that is removed with clear margins, a lumpectomy plus radiation is at least as effective as a mastectomy. For women with small invasive breast cancers, radiation therapy following lumpectomy reduces the likelihood of recurrence by two-thirds.

Prophylactic mastectomy in healthy women with BRCA mutations reduces their risk of breast cancer by 90%. However, it is not clear whether women undergoing this procedure are at lower risk of dying from breast cancer than high-risk women who use careful surveillance methods.

Abnormal results

Abnormal mastectomy results include incomplete removal of the cancer or chronic pain or impairment that does not improve after several months of physical therapy. There is approximately a 9%–10% chance of recurrence following a lumpectomy plus radiation therapy, or recurrence of cancer on the chest wall following a mastectomy.

Morbidity and mortality rates

Morbidity rates are modest. The most common problems include postoperative infection, unwanted scarring, lymphedema, and issues related to emotional adjustment. Mortality is extremely uncommon.

Alternatives

There is no alternative to a medically indicated mastectomy, although breast-conserving surgery is often an option. Alternatives to post-mastectomy reconstructive surgery include the use of pads or breast forms. There are alternatives to prophylactic mastectomy, including genetic testing for BRCA mutations. Women at high risk for breast cancer because of BRCA mutations can use careful surveillance with frequent mammograms. They may also be able to reduce their breast cancer risk by taking tamoxifen or an aromatase inhibitor. In the past, mastectomies were performed on young women with early breast cancer because of the risk of recurrence. However, one large-scale study found that there were no differences in recurrence or survival between young women who had mastectomies and those who had breast-conserving surgery.

KEY TERMS

Areola—The pigmented ring around the nipple.

Aromatase inhibitor—A medication for preventing or treating breast cancer in postmenopausal women by inhibiting the body's production of estrogen.

Axillary lymph nodes—The glands of the lymphatic system located under the arms.

Biopsy—The removal of cells or tissue for examination by a pathologist.

BRCA1, BRCA2—Breast cancer susceptibility genes; specific mutations in these genes greatly increase the risk of breast and ovarian cancers.

Breast-conserving surgery—Breast cancer treatment, such as a lumpectomy or partial mastectomy, that removes only the cancerous tissue rather than the entire breast.

Lobular carcinoma in situ—Breast cancer that is confined to the milk-producing glands.

Lumpectomy—Excision of a breast tumor and a limited amount of surrounding tissue.

Lymph node dissection—The removal of underarm lymph nodes to check for the spread of cancer.

Lymphedema—Accumulation of lymphatic fluid in the soft tissues of the arms, hands, and sometimes the breast area following lymph node dissection.

Mammogram—A breast x ray used to detect cancer.

Margin of resection—The area between the cancerous tumor and the edges of the removed tissue.

Modified radical mastectomy—Total mastectomy with axillary lymph node dissection, but with preservation of the chest muscles.

Partial mastectomy—Segmental mastectomy; removal of only the cancerous breast tissue and some of the surrounding normal tissue.

Prophylactic mastectomy—Removal of a healthy breast to prevent future breast cancer.

Radical mastectomy—Removal of the breast, chest muscles, axillary lymph nodes, and associated skin and subcutaneous tissue.

Skin-sparing mastectomy—Removal of the breast tissue, leaving the skin intact for breast reconstruction.

Tamoxifen—A drug that blocks the activity of estrogen; used to prevent or treat breast cancer.

Tissue-flap surgery—Breast reconstruction using tissues from elsewhere in the body.

Total mastectomy—Simple mastectomy; removal of only the breast tissue, nipple and a small portion of the overlying skin.

Mastitis

Definition

Mastitis is an inflammation within the breast tissue that is usually caused by an infection. It usually only occurs in women who are **breastfeeding** their babies; generally, during the first two months of breast-feeding an infant.

Mastitis is usually caused by a bacterial infection through a nipple damaged during breastfeeding. *(Dr. P. Marazzi/SPL/Photo Researchers, Inc.)*

Demographics

Mastitis usually occurs in lactating mothers. In some cases, it occurs as the result of inflammatory lesions on the breast of females neither pregnant nor breastfeeding. In rare cases it can occur in men.

Description

Breastfeeding is the act of allowing a baby to suckle at the breast to drink the mother's milk. In the process, unaccustomed to the vigorous pull and tug of the infant's suck, the nipples may become sore, cracked, or irritated. This creates a tiny opening in the breast, through which bacteria can enter. The presence of milk, with high sugar content, gives the bacteria an excellent source of **nutrition**. Under these conditions, the bacteria are able to multiply, until they are plentiful enough to cause an infection within the breast.

Mastitis usually begins more than two to four weeks after delivery of the baby. It is a relatively uncommon complication of breastfeeding mothers, occurring in only approximately 3% to 5% of nursing women.

Women are at increased risk from getting mastitis if one or more of the following have occurred:

- Mastitis has occurred previously
- Anemia is present
- Nipples become irritated or cracked. Irritation can be caused by a nursing brassiere (bra) that is too tight

- Breast-feeding is not performed on a regular basis, or if the breasts are not completely emptied of milk during breast-feeding.

Causes and symptoms

Mastitis frequently occurs when bacteria contact a nipple on a female breast, although it can enter the breast from elsewhere. It can also occur due to improper breast-feeding techniques. The most common species of bacteria causing mastitis is *Staphylococcus aureus*; however, it can also be caused by the species *Staphylococcus epidermidis* and certain species within the genus *Streptococci*. In 25% to 30% of people, this bacterium is present on the skin lining of normal, uninfected nostrils. It is probably this bacterium, clinging to the baby's nostrils, that is available to create infection when an opportunity (such as a crack in the nipple or a sore nipple of a nursing mother) presents itself.

Usually, only one breast is involved. An area of the affected breast becomes swollen, tender, red, hard (sometimes lumpy), itchy, and painful (often with a burning sensation). Other symptoms of mastitis include a general feeling of illness, including **fever** (with a temperature equal to or greater than 101°F [38.3°C]), nausea, **vomiting**, aches, shivering and chills, **fatigue**, and increased heart rate. Breast engorgement (enlarged veins and increased pressure due to excess milk production) may also occur. Advanced signs of mastitis includes swollen and tender (or painful) lymph nodes in the armpit adjacent to the infected breast and flu-like symptoms that worsen over time.

Diagnosis

Women should visit their doctor or other healthcare provider as soon as symptoms of mastitis appear, especially if flu-like symptoms appear, along with the presence of a reddish color on one or more of the breasts, breast **pain**, or abnormal leakage of milk from the nipples. Diagnosis by the doctor involves obtaining a sample of breast milk from the infected breast. The milk is cultured, allowing colonies of bacteria to grow. The causative bacteria then can be specially prepared for identification under a microscope. At the same time, tests can be performed to determine what type of antibiotic would be most effective against that particular bacterium. Sometimes, women and their physicians confuse mastitis with breast engorgement, or the tenderness and redness that appear when milk builds up in the breasts. Mastitis often can be distinguished if symptoms are accompanied by fever.

Treatment

A number of **antibiotics** are used to treat mastitis, including cephalexin, amoxicillin, azithromycin, dicloxacillin, and clindamycin. Breastfeeding usually should be continued, because the rate of **abscess** formation (an abscess is a persistent pocket of pus) in the infected breast goes up steeply among women who stop breastfeeding during a bout with mastitis. Most practitioners allow women to take **acetaminophen** (such as Tylenol) or ibuprofen (such as Advil) while nursing, to relieve both fever and pain. As always, breastfeeding women need to make sure that any medication they take is also safe for the baby, since almost all drugs they take appear in the breast milk. Warm compresses applied to the affected breast can be soothing.

Prognosis

Prognosis for uncomplicated mastitis is excellent when it is treated properly with medicine. About 10% of women with mastitis will end up with an abscess within the affected breast. An abscess is a collection of pus within the breast. This complication will require a surgical procedure to drain the pus.

Prevention

The most important aspect of prevention involves good hand-washing to try to prevent the infant from acquiring the *Staphylococcus aureus* bacterium, or another species of bacteria, in the first place. Keeping the breasts, and especially the nipples, clean before breastfeeding also helps prevent infection. Preventing the breasts from becoming engorged may help prevent mastitis by avoid plugging of milk ducts. Breast-feeding often throughout the day is advised. When unable to breast-feed women should use a breast-pump to remove the milk. Placing warm or cold packs on the breasts can also help to relieve the pain.

To make sure all of the milk is extracted from the breast, place a warm, wet washcloth over the affected breast for about 15 to 20 minutes before breast-feeding. Such an action helps to increase the flow of milk out of the nipple during breast-feeding. Other healthcare practices such as getting plenty of rest, drinking sufficient fluids daily, and eating healthy, nutritious meals can also help to avoid fatigue and anemia, which also helps to prevent mastitis. Rather than stopping the act of breastfeeding suddenly it is wise to slowly reduce the amount of times breast-feeding occurs in a day over a several week period.

Mastocytosis

Definition

Mastocytosis is a disease characterized by the presence of too many mast cells in various organs and tissues.

Description

The body has a variety of free-roaming cell populations that function as immunogenic agents. Most immunogenic cells fall into the category of white blood cells, but some remain in tissues and are not found in the blood. Mast cells are such a group.

Mast cells are found primarily in the skin and digestive system, including the liver and spleen, and produce histamine, a chemical most famous for its ability to cause **itching**. Histamine also causes acid **indigestion**, **diarrhea**, flushing, heart pounding, headaches, and can even cause the blood pressure to drop suddenly.

Mastocytosis comes in three forms. Most cases produce symptoms but do not shorten life expectancy. The three forms are:

- Mastocytoma, a benign skin tumor.
- Urticaria pigmentosa, small collections of mast cells in the skin that manifest as salmon or brown-colored patches.
- Systemic mastocytosis, the collection of mast cells in the skin, lymph nodes, liver, spleen, gastrointestinal tract, and bones.

KEY TERMS

Nonsteroidal anti-inflammatory drugs (NSAIDs)—Over-the-counter and prescription medications for reducing pain and inflammation, including aspirin, ibuprofen, naproxen, and many others.

Peptic ulcer—Ulcers in the stomach and upper duodenum (first portion of the small intestine) caused by stomach acid and a bacterium called *Helicobacter pylori*.

Causes and symptoms

The cause of mastocytosis is unknown. People with systemic mastocytosis have bone and joint **pain**. Peptic **ulcers** are frequent because of the increased stomach acid stimulated by histamine. Many patients with systemic mastocytosis also develop urticaria pigmentosa. These **skin lesions** itch when stroked and may become fluid-filled.

Diagnosis

A biopsy of the skin patches aids diagnosis. An elevated level of histamine in the urine or blood is also indicative of mastocytosis.

Treatment

Mastocytoma usually occurs in childhood and clears-up on its own. Urticaria pigmentosa (present alone without systemic disease) also dramatically clears or improves as adolescence approaches.

Several medications are helpful in relieving symptoms of systemic mastocytosis. **Antihistamines** and drugs that reduce stomach acid are frequently needed. Headaches respond to migraine treatment. A medicine called cromolyn helps with the bowel symptoms. Several other standard and experimental medications have been used.

Prognosis

Mastocytoma and urticaria pigmentosa rarely if ever develop into systemic mastocytosis, and both spontaneously improve over time. Systemic mastocytosis is only symptomatically treated. There is no

known treatment that decreases the number of mast cells within tissue.

Mastoid tympanoplasty *see* **Mastoidectomy**

Mastoidectomy

Definition

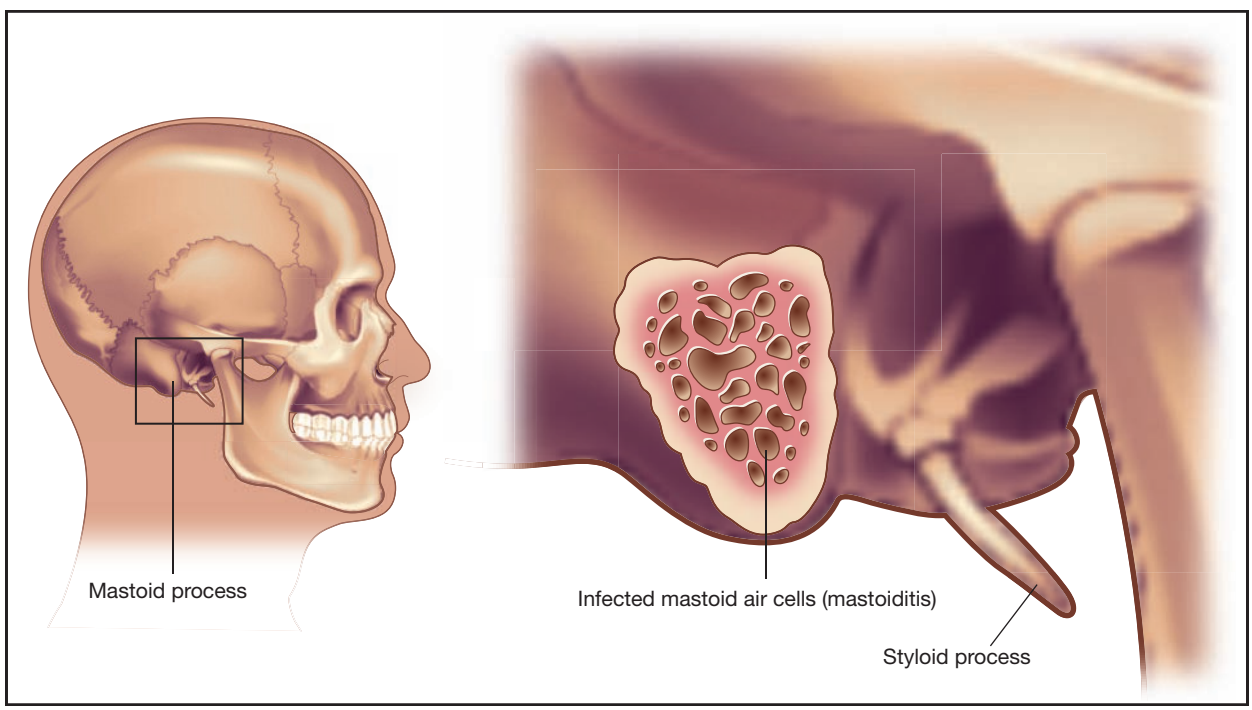
A mastoidectomy is a surgical procedure that removes an infected portion of the mastoid bone when medicinal treatment is not effective.

Purpose

A mastoidectomy is performed to remove infected mastoid air cells resulting from ear infections, such as **mastoiditis** or chronic otitis, or by inflammatory disease of the middle ear (cholesteatoma). The mastoid air cells are open spaces containing air that are located throughout the mastoid bone, the prominent bone located behind the ear that projects from the temporal bone of the skull. The air cells are connected to a cavity in the upper part of the bone, which is in turn connected to the middle ear. Aggressive infections in the middle ear can thus sometimes spread through the mastoid bone. When **antibiotics** can't clear this infection, it may be necessary to remove the infected area by surgery. The primary goal of the surgery is to completely remove infection so as to produce an infection-free ear. Mastoidectomies are also performed sometimes to repair paralyzed facial nerves.

Demographics

Middle ear infections are one of the leading causes of office visits to physicians, and this diagnosis accounts for over 40% of all outpatient antibiotic use. Ear infections are also very common in children between the ages of six months and two years. According to the American Academy of Otolaryngology—Head and Neck Surgery, almost 100% of children in developed countries have at least one ear infection by their fifth birthday.



A mastoidectomy is done to treat severe mastoiditis, an infection of the mastoid cells. *(Illustration by Electronic Illustrators Group. Copyright © 2014 Cengage Learning®.)*

WWW.BOOKBAZ.IR

Description

An mastoidectomy is performed in a hospital by surgeons specialized in otolaryngology, the branch of medicine concerned with the diagnosis and treatment of disorders and diseases of the ears, nose, and throat. The procedure usually takes between two and three hours. It is occasionally performed on an outpatient basis in adults but usually involves hospitalization.

A mastoidectomy is performed with the patient fully asleep under general **anesthesia**. There are several different types of mastoidectomy procedures, depending on the amount of infection present:

- Simple (or closed) mastoidectomy. The operation is performed through the ear or through a cut (incision) behind the ear. The surgeon opens the mastoid bone and removes the infected air cells. The eardrum is incised to drain the middle ear. Topical antibiotics are then placed in the ear.
- Radical mastoidectomy. The procedure removes the most bone and is usually performed for extensive spread of a cholesteatoma. The eardrum and middle ear structures may be completely removed. Usually the stapes, the stirrup-shaped bone, is spared if possible to help preserve some hearing.
- Modified radical mastoidectomy. In this procedure, some middle ear bones are left in place and the eardrum is rebuilt by tympanoplasty.

After surgery, the wound is stitched up around a drainage tube and a dressing is applied.

Diagnosis

The treating physician gives the patient a thorough ear, nose, and throat examination and uses detailed diagnostic tests, including an audiogram and imaging studies of the mastoid bone, using x rays or CT scans to evaluate the patient for surgery.

Preparation

The patient is prepared for surgery by shaving the hair behind the ear on the mastoid bone. Mild soap and water solutions are commonly used to cleanse the outer ear and surrounding skin.

Aftercare

The drainage tube inserted during surgery is typically removed a day or two later.

Painkillers are usually needed for the first day or two after the operation. The patient should drink fluids freely. After the stitches are removed, the bulky mastoid dressing can be replaced with a smaller dressing if the ear is still draining. The patient is given antibiotics for several days.

The patient should inform the physician if any of the following symptoms occur:

- bright red blood on the dressing
- stiff neck or disorientation (may be signs of meningitis)
- facial paralysis, drooping mouth, or problems swallowing

Risks

Complications do not often occur, but they may include:

- persistent ear discharge
- infections, including meningitis or brain abscesses
- hearing loss
- facial nerve injury (a rare complication)
- temporary dizziness
- temporary loss of taste on the side of the tongue

Results

The outcome of a mastoidectomy is a clean, healthy ear without infection. However, both a modified radical and a radical mastoidectomy usually result in less than normal hearing. After surgery, a hearing aid may be considered if the patient so chooses.

Morbidity and mortality rates

In the United States, death from intracranial complications of cholesteatoma is uncommon due to earlier recognition, timely surgical intervention, and supportive antibiotic therapy. Cholesteatoma remains a relatively common cause of permanent, moderate, and conductive **hearing loss**.

Alternatives

Alternatives to mastoidectomy include the use of medications and delaying surgery. However, these alternative methods carry their own risk of complications and a varying degree of success. Thus, most physicians are of the opinion that patients for whom mastoidectomy is indicated should best undergo the operation, as it provides the patient with the best chance of successful treatment and the lowest risk of complications.

KEY TERMS

Audiogram—A test of hearing at a range of sound frequencies.

Mastoid air cells—Numerous small intercommunicating cavities in the mastoid process of the temporal bone that empty into the mastoid antrum.

Mastoid antrum—A cavity in the temporal bone of the skull, communicating with the mastoid cells and with the middle ear.

Mastoid bone—The prominent bone behind the ear that projects from the temporal bone of the skull.

Mastoiditis—An inflammation of the bone behind the ear (the mastoid bone) caused by an infection spreading from the middle ear to the cavity in the mastoid bone.

Otitis—Inflammation of the ear, which may be marked by pain, fever, abnormalities of hearing, hearing loss, tinnitus, and vertigo.

Tympanoplasty—Procedure to reconstruct the tympanic membrane (eardrum) and/or middle ear bone as the result of infection or trauma.

Mastoiditis

Definition

Mastoiditis is an infection of the spaces within the mastoid bone (located immediately behind the outside ear) within the skull. It is usually associated with **otitis media**, an infection of the middle ear. In the most serious cases, the bone itself becomes infected.

Demographics

Mastoiditis occurs in humans at any age, and equally of males and females. However, it is more likely to occur in children, primarily in younger children from six months to about one year of age. It rarely occurs in developed countries, such as the United States. Its incidence in the United States is usually less than four out of 100,000 people (0.004%) annually.

Description

The mastoid is a part of the side (temporal bone) of the skull. It can be felt as a bony bump just behind and slightly above the level of the earlobe. The mastoid has been described as resembling a "honeycomb" of tiny partitioned-off airspaces. The mastoid is connected with the middle ear, so that when there is a collection of fluid in the middle ear, there is usually also a slight collection of fluid within the airspaces of the mastoid.

Mastoiditis can range from a simple case of some fluid escaping into the mastoid air cells during a middle ear infection, to a more complex infection which penetrates through to the lining of the mastoid bone, to a very severe and destructive infection of the mastoid bone itself.

Increased complications after getting mastoiditis may include:

- Paralysis of the face
- Meningitis (inflammation of the meninges)
- Hearing loss
- Infection extending throughout the body

WWW.BOOKBAZ.IR

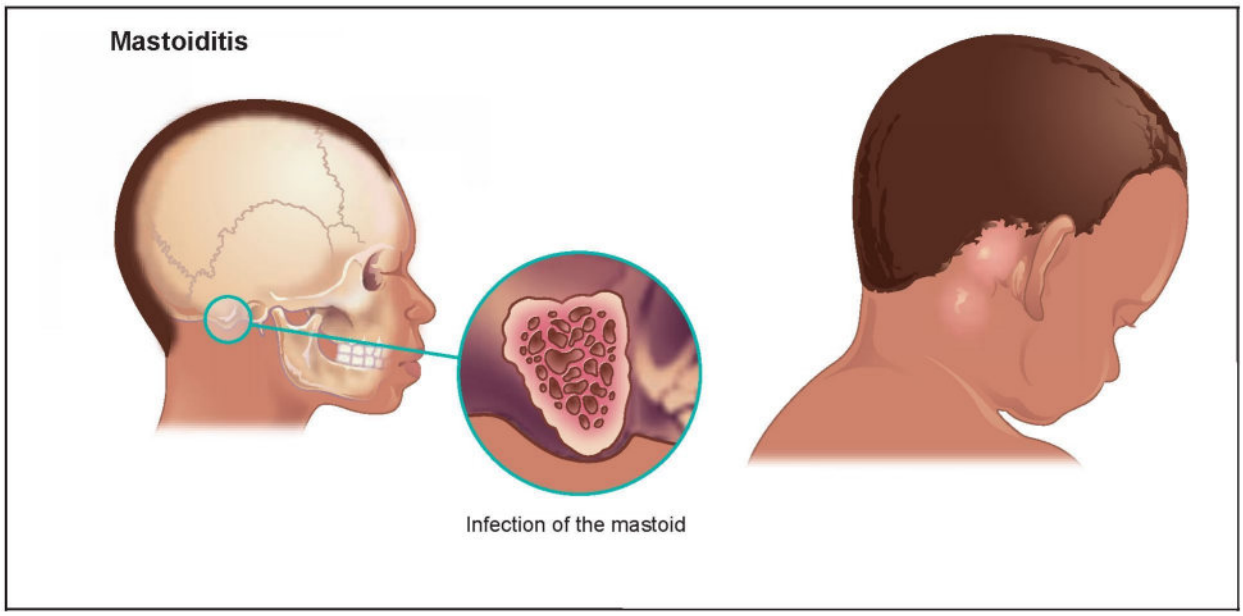

Illustration depicting infection of the mastoid (part of the temporal bone in the skull), and the appearance of the infection on the surface of the skin. *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

- Vertigo (dizziness when stationary)
- Damaged or destroyed mastoid bone
- Epidural abscess

Causes and symptoms

Mastoiditis is caused by the same types of bacteria that cause middle ear infections (*Streptococcus pneumoniae* and *Haemophilus influenzae*), as well as by a variety of other bacteria (*Staphylococcus aureus*, *Pseuodomonas aeruginosa*, *Klebsiella*, *Escherichia coli*, *Proteus*, *Prevotella*, *Fusobacterium*, *Porphyromonas*, and *Bacteroides*). Mastoiditis may occur due to the progression of an untreated, or undertreated, middle ear infection (what is called acute otitis media). The infection most often occurs in children.

Symptoms of mastoiditis may at first be the same as symptoms of an early middle ear infection. With progression, however, the swollen mastoid may push the outer ear slightly forward and away from the head. The area behind the ear will appear red and swollen, and will be very sore. **Fever** is usually present and appears suddenly in most cases. A **headache** frequently is a symptom. There may be drainage of pus from the infected ear. In some cases, the skin over the mastoid may develop an opening through which pus drains. The reduced ability to hear may also occur. In infants, the symptoms can include irritability, **diarrhea**, fever, and poor feeding.

Diagnosis

Mastoiditis is usually suspected by a family physician or an ear, nose, and throat (ENT) specialist when a severe middle ear infection is accompanied by redness, swelling, and **pain** in the mastoid area. A **magnetic resonance imaging** (MRI) scan may be used, or a computed tomography (CT) scan may also be used; both show inflammation and fluid within the airspaces of the mastoid, as well as the erosion of the little walls of bone that should separate the air spaces. Several head and skull CT scans may be requested. If fluid drains from the ear or mastoid, a culture of the drainage will allow a laboratory to indentify the causative organism. If there is no fluid available, a tiny needle can be used to obtain a sample of the fluid which has accumulated behind the eardrum.

Treatment

Identification of the causative organism guides the practitioner's choice of antibiotic. Depending on the severity of the infection, the antibiotic can be given initially through a needle in the vein (intravenously, or IV), and then (as the patient improves) by mouth. Oftentimes, long-term treatment, or repeat treatment, of **antibiotics** is necessary. The group of antibiotics called penicillin may be used unless the patient is allergic to it. In such cases, clindamycin may be used.

In the case of a very severe infection of the mastoid bone itself, with a collection of pus (**abscess**), an

KEY TERMS

Abscess—A pocket of infection, usually including a collection of pus.

Meningitis—Inflammation and infection of the tissues covering the brain and spinal cord (the meninges).

Otitis (or oteitis)—An infection of the middle ear; marked by an enlargement of bone, tenderness and dull aching pain.

operation to remove the mastoid part of the temporal bone is often necessary (**mastoidectomy**). Surgery to drain the middle ear is often performed to solve the problem with the middle ear infection.

Prognosis

With early identification of mastoiditis, the prognosis is very good. Sometimes it is difficult to make sure the antibiotics reach the interior of the mastoid area. In this case, the prognosis is less positive. When symptoms are not caught early enough, however, a number of complications can occur. These include an infection of the tissues covering the brain and spinal cord (**meningitis**), a pocket of infection within the brain (abscess), or an abscess within the muscles of the neck. All of these complications have potentially more serious prognoses. With the use of antibiotics, mastoiditis has become a minor ailment, only infrequently occurring in the United States. However, before antibiotics were discovered, it could easily cause death. In fact, at one time mastoiditis was one of the primary causes of death among children.

Prevention

Prevention of mastoiditis involves careful and complete treatment of any middle ear infections.

Maternal obesity

Definition

Maternal **obesity** occurs when a woman becomes overweight to the point of being obese during her **pregnancy** and/or the period one year after the birth of her child (one year postpartum). Maternal obesity is associated with an increased risk of numerous health problems for both the mother and her infant. Some of those health problems may not appear until later in life.

Description

Obesity is typically described using **body mass index** (BMI), which is an individual's weight in kilograms (kg) divided by the square of that person's height in meters (m^2). Using this measurement, obesity is considered to be a BMI of 30 kg/m^2 or more. In contrast, overweight is considered to a BMI of 25–29.9 kg/m^2, and extreme obesity is considered to be a BMI of 40 kg/m^2 or more.

Maternal obesity increases the risks for numerous health conditions in mothers. These include:

- preeclampsia, or gestational proteinuric hypertension, which is a pregnancy-related condition characterized by excess protein in the urine and high blood pressure
- gestational diabetes mellitus, which is the occurrence of high blood glucose levels in pregnant women who did not have type 1 or type 2 diabetes previously
- complications during labor and delivery, which may lead to cesarean section, which is delivery of a baby through incisions in the mother's abdomen, rather than via normal vaginal delivery
- obesity later in life
- heart disease later in life

- hypertension later in life
- type 2 diabetes later in life

Maternal obesity also has implications for the baby. It increases the risks for a variety of health conditions, including the following:

- stillbirth (compared with normal-weight women, women who are maternally obese have about twice the risk of stillbirth, which may be due to increased incidence of hypertension and/or gestational diabetes mellitus)
- congenital anomalies or birth defects, including the neural tube deficit spinal bifida, which is an incomplete development of the brain, spinal cord, and/or the protective covering (meninges) surrounding them.
- fetal macrosomia, a fetal weight of 4,500 g or more, which is associated with an increased risk for other health problems
- perinatal mortality, which includes stillbirth and death of a newborn (maternal obesity is associated with a four-fold increase in perinatal mortality)
- shoulder dystocia, which is a shoulder injury that can occur when the fetus's shoulders become pressed against the bones of the mother's pelvis during delivery
- obesity later in life (this is particularly related to maternal obesity in the first trimester)
- heart disease later in life
- type 2 diabetes mellitus later in life

Risk factors

Risk factors for obesity overall are complex, and that is also the case for maternal obesity. Physical activity, diet, and state of mental and physical health can all play a role in maternal obesity. In addition, since maternal obesity can impact the infant, a woman's likelihood of becoming obese during her pregnancy or within a year of delivering her baby may also be related to whether her own mother was maternally obese while carrying her.

Demographics

According to a 2013 report of the American College of Obstetricians and Gynecologists, more than half of pregnant women are overweight or obese.

Causes and symptoms

Diet, physical activity, physical and mental state, and patient history (including whether the pregnant woman's own mother was maternally obese) may all participate in maternal obesity.

Maternal obesity can result in many issues for the mother, including **preeclampsia** and **gestational diabetes** mellitus, and may also result in the delivery being **cesarean section** rather than a normal vaginal birth.

Preeclampsia

For every 5–7 kg/m^2 increase in BMI, a woman has a two-fold escalation in her risk of developing preeclampsia.

Gestational diabetes mellitus

Compared to normal-weight women, the rate of gestational **diabetes mellitus** more than doubles for

women who are overweight, quadruples for women who are obese, and increases by more than eight times for those who are severely obese.

Cesarean section

A successful vaginal delivery is inversely proportional to BMI: As BMI increases, successful vaginal delivery decreases. Compared to normal-weight women, the rate of Cesarean births is more than double for women who are extremely obese. In addition, the likelihood that a woman will have a successful subsequent vaginal birth after Cesarean (VBAC) falls as BMI increases. From a rate of nearly 85 % for normal-weight women, the rate of VBAC drops to less than 55 % for women who are maternally obese.

Maternal obesity can also cause health issues for infants, such as fetal macrosomia, **spina bifida**, and shoulder dystocia.

Fetal macrosomia

In fetal macrosomia, fetuses weigh 4500 g or more. Women with a normal BMI—less than 25 kg/m^2—have infants with a body fat composition of 9.7% vs. women who have a BMI of 25 kg/m^2 or higher, who have infants with a body fat composition of 11.6%. This may be due, in part, to an increase in fats available from the mother during fetal growth and development. Research studies have associated higher birthweights—4 kg (9 pounds) or more—with the development of obesity, diabetes, **heart disease**, and cancer over the child's lifetime. Studies have even shown that high birthweight is related to neurological problems, including a higher propensity for become overly stressed in old age, and possibly for developing **schizophrenia**.

Neural tube deficit

A 1 kg/m^2 increase in the mother's BMI is associated with a 7% rise in neural tube deficit. Although the reason for the escalated risk is still not completely known, it is thought to be related to lack of sufficient **folic acid** reaching the embryo. This may result from heightened demands for folic acid from the mother's body, increased circulating levels of insulin in the mother's body, or other factors related to maternal obesity.

Shoulder dystocia

Maternal obesity is more likely to give rise to large fetuses. Although shoulder dystocia is rare, larger babies do have an increased risk of sustaining injury to the shoulders during delivery. While a larger baby's head may pass through the birth canal properly, the shoulders have an increased risk of becoming hung up on the mother's pelvic bones and pressed against them, which can result in injury.

Diagnosis

Unless the woman is an athlete or body builder, which would skew the results, BMI is the typical measurement used to determine whether a woman is maternally obese. If a woman's BMI falls at or above 30 kg/m^2, maternal obesity is diagnosed.

Treatment

The physician will typically recommend dietary changes and an increase in physical activity to return a woman's BMI to normal levels. Women should consult their doctor about a healthy diet, and should not take any weight-reduction medications or over-the counter remedies without first consulting with the physician, as some of these medications and remedies can affect her health or that of the fetus/infant.

Prognosis

Although some women and their babies do not have adverse outcomes stemming from maternal obesity, many do. Of those women who have gestational diabetes mellitus, a condition that is more likely among women with maternal obesity, more than 50% will go on to develop diabetes within 20 years. Maternal obesity is also associated with a higher risk for obesity, **hypertension**, cardiovascular disease, and other conditions in both the women and their children. Many of these conditions result in a lower quality of life, and some can be fatal.

Prevention

A nutritional diet and physical activity can help a woman maintain a healthy weight during and after her pregnancy. Women should begin consulting their doctors when they are first considering having a baby, so that they not only enter pregnancy at a healthy weight, but also know how to maintain a healthy weight throughout and after their pregnancy. Likewise, doctors should take it upon themselves to promote a healthy weight, diet, and lifestyle to female patients of childbearing age, especially those who are pregnant or who are considering becoming pregnant.

KEY TERMS

Cesarean section—The delivery of a baby through an incision in the mother's abdomen, rather than via normal vaginal delivery.

Gestational diabetes mellitus—The occurrence of high blood glucose levels in pregnant, previously non-diabetic women.

Neural tube deficit—A defect in an embryo's neural tube, which develops into the spinal cord and brain/

Preeclampsia—Also known as gestational proteinuric hypertension, preeclampsia is a pregnancy-related condition characterized by excess protein in the urine and high blood pressure.

Spinal bifida—A neural tube deficit tjat causes an incomplete development of the brain, spinal cord, and/or the protective covering (meninges) surrounding them.

Maxillofacial trauma

Definition

Maxillofacial **trauma** refers to any injury to the face or jaw caused by physical force, **foreign objects**, or **burns**.

Description

Maxillofacial trauma includes injuries to any of the bony or fleshy structures of the face.

Any part of the face may be affected. Teeth may be knocked out or loosened. The eyes and their muscles, nerves, and blood vessels may be injured as well as the eye socket (orbit), which can be fractured by a forceful blow. The lower jaw (mandible) may be dislocated by force. Although anchored by strong muscles for chewing, the jaw is unstable in comparison with other bones and is easily dislocated from the temporomandibular joints that attach it to the skull. A fractured nose or jaw may affect the ability to breathe or eat. Any maxillofacial trauma may also prevent the passage of air or be severe enough to cause a **concussion** or more serious brain injury.

Athletes are particularly at risk of maxillofacial injuries. Boxers suffer repeated blows to the face and occasional knockouts (**traumatic brain injury**). Football, basketball, hockey, and soccer players, and many other athletes are at risk for milder forms of brain injury called concussions. There are an estimated 300,000 cases every year. Overall, there are one million new traumatic brain injuries every year, causing 50,000 deaths. Of the rest, seven to nine percent are left with long-term disability.

Burns to the face are also categorized as maxillofacial trauma.

Causes and symptoms

There are no reliable statistics on the incidence of maxillofacial trauma because there are so many types, and many are not reported. Automobile accidents are a major cause of maxillofacial trauma, as is participation in sports, fights, and other violent acts. Another cause of such injuries is being hit by an object accidentally, for instance being hit by a baseball while watching a game. People most at risk are athletes, anyone who drives a vehicle or rides in one, and those who do dangerous work or engage in aggressive types of behavior.

One study reported in August 2000 that 42% of all facial **fractures** resulted from sports activity.

The major symptoms of most facial injuries are **pain**, swelling, bleeding, and bruising, although a fractured jaw also prevents the person from working his or her jaw properly, and symptoms of a fractured nose also include black eyes and possible blockage of the airway due to swelling and bleeding.

Symptoms of eye injury or orbital fracture can include blurred or double vision, decreased mobility of the eye, and numbness in the area of the eye. In severe injuries there can be temporary or permanent loss of vision.

Burn symptoms are pain, redness, and possibly blisters, **fever**, and **headache**. Extensive burns can cause the victim to go into **shock**. In that situation, he or she has low blood pressure and a rapid pulse.

Symptoms of traumatic brain injury include problems with thinking, memory, and judgment as well as mood swings, and difficulty with coordination and balance. These symptoms linger for weeks or months, and in severe cases can be permanent. Double vision for months after an injury is not uncommon.

Diagnosis

Trauma is usually diagnosed in an emergency room or physician's office by **physical examination** and/or x ray. Some injuries require diagnosis by a specialist. A detailed report of how the injury occurred is also taken. In some cases, diagnosis cannot be made until swelling subsides.

Treatment

Treatment varies, depending on the type and extent of the injury.

WWW.BOOKBAZ.IR

Dislocation of the jaw can be treated by a primary care physician by exerting pressure in the proper manner. If muscle spasm prevents the jaw from moving back into alignment, a sedative is administered intravenously (IV) to relax the muscles. Afterward, the patient must avoid opening the jaw wide as he or she will be prone to repeat **dislocations**.

A jaw fracture may be minor enough to heal with simple limitation of movement and time. More serious fractures require complicated, multi-step treatment. The jaw must be surgically immobilized by a qualified oral or maxillofacial surgeon or an otolaryngologist. The jaw is properly aligned and secured with metal pins and wires. Proper alignment is necessary to ensure that the bite is correct. If the bite is off, the patient may develop a painful disorder called temporomandibular joint syndrome.

During the weeks of healing the patient is limited to a liquid diet sipped through a straw and must be careful not to choke or vomit since he or she cannot open the mouth to expel the vomitus. The surgeon will prescribe pain relievers and perhaps **muscle relaxants**. Healing time varies according to the patient's overall health, but will take at least several weeks.

Another common maxillofacial fracture is a broken nose. The bones that form the bridge of the nose may be fractured, but cartilage may also be damaged, particularly the nasal septum which divides the nose. If hit from the side, the bones and cartilage are displaced to the side, but if hit from the front, they are splayed out. Severe swelling can inhibit diagnosis and treatment. Mild trauma to the nose can sometimes heal without the person' being aware of the fracture unless there is obvious deformity. The nose will be tender for at least three weeks.

Either before the swelling begins or after it subsides, some 10 days after the injury, the doctor can assess the extent of the damage. Physical examination of the inside using a speculum and the outside, in addition to a detailed history of how the injury occurred will determine appropriate treatment. The doctor should be informed of any previous nasal fractures, nasal surgery, or chronic disease such as **osteoporosis**. Sometimes an x ray is useful, but it is not always required.

A primary care physician may treat a nasal fracture, but if there is extensive damage or the air passage is blocked, the physician will refer the patient to an otolaryngologist or a plastic surgeon for treatment. Initially the nose may be packed to control bleeding and hold the shape. It is reset under **anesthesia**. A protective shield or bandage may be placed over it while the fracture heals.

In the case of orbital fractures, there is great danger of permanent damage to vision. Double vision and decreased mobility of the eye are common complications. Surgical reconstruction may be required if the fracture changes the position of the eye or there is other facial deformity. Treatment requires a maxillofacial surgeon.

When the eyes have been exposed to chemicals, they must be washed out for 15 minutes with clear water. **Contact lenses** may be removed only after rinsing the eyes. The eyes should then be kept covered until the person can be evaluated by a primary care physician or ophthalmologist.

When a foreign object is lodged in the eye, the person should not rub the eye or put pressure on it, which would further injure the eyeball. The eye should be covered to protect it until medical attention can be obtained.

Several kinds of traumatic injuries can occur to the mouth. A person can suffer a laceration (cut) to the lips or tongue, or loosening of teeth, or have teeth knocked out. Such injuries often accompany a jaw fracture or other facial injury. **Wounds** to the soft tissues of the mouth bleed freely, but the plentiful blood supply that leads to this heavy bleeding also helps healing. It is important to clean the wound thoroughly with salt water or hydrogen peroxide rinse to prevent infection. Large cuts may require sutures, and should be done by a maxillofacial surgeon for a good cosmetic result, particularly when the laceration is on the edge of the lip line (vermilion). The doctor will prescribe an antibiotic because there is normally a large amount of bacteria present in the mouth.

Any injury to the teeth should be evaluated by a dentist for treatment and prevention of infection. Implantation of a tooth is sometimes possible if it has been handled carefully and protected. The tooth should be held by the crown, not the root, and kept in milk, saline, or contact lens fluid. The patient's dentist can refer him or her to a specialist in this field.

For first degree burns, put a cold-water compress on the area or run cold water on it. Put a clean bandage on it for protection. Second and third degree burn victims must be taken to the hospital for treatment.

Fluids are replaced there through an IV. This is vital since a patient in shock will die unless lost fluids are replaced quickly. **Antibiotics** are given to combat infection since burns make the body vulnerable to infection.

Treatment for a **head injury** requires examination by a primary care physician unless symptoms point to

KEY TERMS

Corneal abrasion—A scratch on the surface of the eyeball.

Mandible—The lower jaw, a U–shaped bone attached to the skull at the temporomandibular joints.

Maxilla—The bone of the upper jaw, which serves as a foundation of the face and supports the orbits.

Nasal septum—The cartilage that separates the nostrils.

Orbit—The eye socket, which contains the eyeball, muscles, nerves, and blood vessels that serve the eye.

Otolaryngologist—Ear, nose, and throat specialist.

Shock—A reduction of blood flow in the body caused by loss of blood and/or fluids. Shock can be fatal if not treated quickly.

Temporomandibular joint (TMJ)—The joint that attaches the mandible to the temporal bone of the skull and works like a hinge.

Temporomandibular joint syndrome (TMJ syndrome)—An incorrect alignment of the lower jaw to the skull that causes the bite to be off line. It causes chronic headaches, nausea, and other symptoms.

Vermilion border—The line between the lip and the skin.

a more serious injury. In that case, the victim must seek emergency care. A concussion is treated with rest and avoidance of contact sports. Very often athletes who have suffered a concussion are allowed to play again too soon, perhaps in the mistaken impression that the injury is not so bad if the player did not lose consciousness. Anyone who has had one concussion is at increased risk of another one.

Danger signs that the injury is more serious include worsening headaches, **vomiting**, weakness, numbness, unsteadiness, change in the appearance of the eyes, seizures, slurred speech, confusion, agitation, or the victim will not wake up. These signs require immediate transport to the hospital. A neurologist will evaluate the situation, usually with a CT scan. A stay in a **rehabilitation** facility may become necessary.

Alternatives

Fractures, burns, and deep lacerations require treatment by a doctor but alternative treatments can help the body withstand injury and assist the healing process. **Calcium**, **minerals**, **vitamins**, all part of a balanced and nutrient–rich diet, as well as regular **exercise**, build strong bones that can withstand force well. After an injury, **craniosacral therapy** may help healing and ease the headaches that follow a concussion or other head trauma. A physical therapist can offer **ultrasound** that raises temperature to ease pain, or **biofeedback** in which the patient learns how to tense and relax muscles to relieve pain. **Hydrotherapy** may ease the **stress** of recovering from trauma. Chinese medicine seeks to reconnect the chi along the body's meridians and thus aid healing. Homeopathic physicians may prescribe natural medicines such as Arnica or Symphytum to enhance healing.

Prognosis

When appropriate treatment is obtained quickly after an injury, the prognosis can be excellent. However, if the victim of trauma has osteoporosis or a debilitating chronic disease, healing is more problematic. Healing also depends upon the extent of the injury. An automobile accident or a gunshot wound, for example, can cause severe facial trauma that may require multiple surgical procedures and a considerable amount of time to heal. Burns and lacerations cause scarring that might be improved by **plastic surgery**.

Prevention

Safety equipment is vital to preventing maxillofacial trauma from automobile accidents and sports. Here is a partial list of equipment people should always use:

- seat belts
- automobile air bags
- approved child safety seats
- helmets for riding motorcycles or bicycles, skateboarding, snowboarding, and other sports
- safety glasses for the job, yard work, sports
- other approved safety equipment for sports, such as mouthguards, masks, and goggles

Measles

Definition

Measles is an infection caused by a virus, which causes a characteristic skin rash known as an exanthem. Measles is also sometimes called rubeola, 5-day measles, or hard measles.

Description

Measles infections appear all over the world. Prior to the current effective immunization program, large-scale measles outbreaks occurred on a two to three-year cycle, usually in the winter and spring. Smaller outbreaks occurred during the off-years. Babies up to about eight months of age are usually protected from contracting measles, due to immune cells they receive from their mothers in the uterus. Once individuals have had measles infection, they can never get it again.

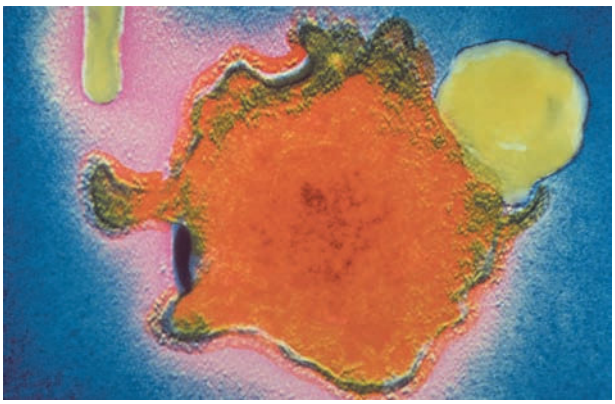
Causes and symptoms

Measles is caused by a type of virus called a paramyxovirus. It is an extremely contagious infection, spread through the tiny droplets that may spray into the air when an individual carrying the virus sneezes or coughs. About 85% of those people exposed to the virus will become infected with it. About 95% of those people infected with the virus will develop the illness called measles. Once individuals are infected with the virus, it takes about 7–18 days before they actually becomes ill. The most contagious time period is the three to five days before symptoms begin through about four days after the characteristic measles rash has begun to appear.

The first signs of measles infection are **fever**, extremely runny nose, red, runny eyes, and a **cough**. A few days later, a rash appears in the mouth, particularly on the mucous membrane which lines the cheeks. This rash consists of tiny white dots (like grains of salt or sand) on a reddish bump. These are called Koplik's spots, and are unique to measles infection. The throat becomes red, swollen, and sore.

A couple of days after the appearance of the Koplik's spots, the measles rash begins. It appears in a characteristic progression, from the head, face, and neck, to the trunk, then abdomen, and next out along the arms and legs. The rash starts out as flat, red patches, but eventually develops some bumps. The rash may be somewhat itchy. When the rash begins to appear, the fever usually climbs higher, sometimes reaching as high as 105°F (40.5°C). There may be nausea, **vomiting**, **diarrhea**, and multiple swollen lymph nodes. The cough is usually more problematic at this point, and the patient feels awful. The rash usually lasts about five days. As it fades, it turns a brownish color, and eventually the affected skin becomes dry and flaky.

Many patients (about 5–15%) develop other complications. Bacterial infections, such as ear infections, sinus infections, and **pneumonia** are common, especially in children. Other viral infections may also strike the patient, including **croup**, **bronchitis**, **laryngitis**, or viral pneumonia. Inflammation of the liver, appendix, intestine, or lymph nodes within the abdomen may cause other complications. Rarely, inflammations of the heart or kidneys, a drop in **platelet count** (causing episodes of difficult-to-control bleeding), or reactivation of an old **tuberculosis** infection can occur.



A transmission electron microscopy (TEM) image of a single measles virion. *(Custom Medical Stock Photo, Inc.)*

An extremely serious complication of measles infection is swelling of the brain. Called encephalitis, this condition can occur up to several weeks after the basic measles symptoms have resolved. About one out of every thousand patients develops this complication, and about 10-15% of these patients die. Symptoms include fever, **headache**, sleepiness, seizures, and **coma**. Long-term problems following recovery from measles encephalitis may include seizures and mental retardation.

A very rare complication of measles can occur up to 10 years following the initial infection. Called **subacute sclerosing panencephalitis**, this is a slowly progressing, smoldering swelling and destruction of the entire brain. It is most common among people who had measles infection prior to the age of two years. Symptoms include changes in personality, decreased intelligence with accompanying school problems, decreased coordination, involuntary jerks and movements of the body. The disease progresses so that individuals become increasingly dependent, ultimately bedridden and unaware of their surroundings. Blindness may develop, and the temperature may spike (rise rapidly) and fall unpredictably as the brain structures responsible for temperature regulation are affected. Death is inevitable.

Measles during **pregnancy** is a serious disease, leading to increased risk of a **miscarriage** or **stillbirth**. In addition, the mother's illness may progress to pneumonia.

Diagnosis

Measles infection is almost always diagnosed based on its characteristic symptoms, including Koplik's spots, and a rash which spreads from central body structures out toward the arms and legs. If there is any doubt as to the diagnosis, then a specimen of body fluids (mucus, urine) can be collected and combined with fluorescent-tagged measles virus antibodies. Antibodies are produced by the body's immune cells that can recognize and bind to markers (antigens) on the outside of specific organisms, in this case the measles virus. Once the fluorescent antibodies have attached themselves to the measles antigens in the specimen, the specimen can be viewed under a special microscope to verify the presence of measles virus.

Treatment

There are no treatments available to stop measles infection. Treatment is primarily aimed at helping the patient to be as comfortable as possible, and watching carefully so that **antibiotics** can be started promptly if a bacterial infection develops. Fever and discomfort can be treated with **acetaminophen**. Children with measles should never be given **aspirin**, as this has caused the fatal disease Reye's syndrome in the past. A cool-mist vaporizer may help decrease the cough. Patients should be given a lot of liquids to drink, in order to avoid **dehydration** from the fever.

Some studies have shown that children with measles encephalitis benefit from relatively large doses of **vitamin A**.

Alternatives

Botanical immune enhancement (with **echinacea**, for example) can assist the body in working through this viral infection. Homeopathic support also can be effective throughout the course of the illness. Some specific alternative treatments to soothe patients with measles include the Chinese herbs bupleurum (*Bupleurum chinense*) and peppermint (*Mentha piperita*), as well as a preparation made from empty cicada (*Cryptotympana atrata*) shells. The itchiness of the rash can be relieved with witch hazel (*Hamamelis virginiana*), chickweed (*Stellaria media*), or oatmeal baths. The eyes can be soothed with an eyewash made from the herb eyebright (*Euphrasia officinalis*). Practitioners of **ayurvedic medicine** recommend ginger or clove tea.

Prognosis

The prognosis for an otherwise healthy, well-nourished child who contracts measles is usually quite good. In developing countries, however, death rates may reach 15–25%. Adolescents and adults usually have a more difficult course. Women who contract the disease while pregnant may give birth to a baby with hearing impairment. Although only 1 in 1,000 patients with

Encephalitis—Swelling, inflammation of the brain.

Exanthem (plural, exanthems or exanthemata)—A skin eruption regarded as a characteristic sign of such diseases as measles, German measles, and scarlet fever.

measles will develop encephalitis, 10–15% of those who do will die, and about another 25% will be left with permanent brain damage.

Prevention

Measles is a highly preventable infection. A very effective vaccine exists, made of live measles viruses which have been treated so that they cannot cause actual infection. The important markers on the viruses are intact, however, which causes an individual's immune system to react. Immune cells called antibodies are produced, which in the event of a future infection with measles virus will quickly recognize the organism, and kill it off. Measles vaccines are usually given at about 15 months of age; because prior to that age, the baby's immune system is not mature enough to initiate a reaction strong enough to insure long-term protection from the virus. A repeat injection should be given at about 10 or 11 years of age. Outbreaks on college campuses have occurred among unimmunized or incorrectly immunized students.

Measles vaccine should not be given to a pregnant woman, however, in spite of the seriousness of gestational measles. The reason for not giving this particular vaccine during pregnancy is the risk of transmitting measles to the unborn child.

Surprisingly, new cases of measles began being reported in some countries—including Great Britain—in 2001 because of parents' fears about vaccine safety. The combined vaccine for measles, **mumps**, and **rubella** (MMR) was claimed to cause **autism** or bowel disorders in some children. However, the World Health Organization (WHO) says there is no scientific merit to these claims. The United Nations expressed concern that unwarranted fear of the vaccine would begin spreading the disease in developing countries, and ultimately in developed countries as well. Parents in Britain began demanding the measles vaccine as a separate dose, and scientists were exploring that option as an alternative to the combined MMR vaccine. Unfortunately, several children died during an outbreak of measles in Dublin because they had not received the vaccine. Child mortality due to measles is considered largely preventable, and making the MMR vaccine widely available in developing countries is part of WHO's strategy to reduce child mortality by two-thirds by the year 2015.

Measles was declared to have been eliminated in the United States in 2000, largely as a result of the effective **vaccination** campaign against the disease. Some cases continue to be reported, however, because the disease still occurs widely throughout the world, and travelers to other countries are sometimes infected there. They then come down with the disease after they have returned to the United States. Between 2000 and 2012, an average of 60 measles cases annually were reported in the United States as a consequence of foreign infection. In 2013, however, that number began to rise significantly, and 159 cases of measles were reported to the CDC between January 1 and August 24. Of that number, at least 82 percent, and perhaps as many as 91 percent, of those who developed the disease had not been vaccinated against it. Health officials are increasingly concerned about the unnecessary risk to which children are put when parents decide against having their children vaccinated with the MMR vaccine.

Meckel's diverticulum

Definition

Meckel's diverticulum is a congenital pouch (diverticulum) approximately two inches in length and located at the lower (distal) end of the small intestine. It was named for Johann F. Meckel, a German anatomist who first described the structure.

Description

The diverticulum is most easily described as a blind pouch that is a remnant of the omphalomesenteric duct or yolk sac that nourished the early embryo. It contains all layers of the intestine and may have ectopic tissue present from either the pancreas or stomach.

The rule of 2s is the classical description. It is located about 2 feet from the end of the small intestine, is often about 2 inches in length, occurs in about 2% of the population, is twice as common in males as females, and can contain two types of ectopic tissue—stomach or pancreas. Many who have a Meckel's diverticulum never have trouble but those that do present in the first two decades of life and often in the first two years.

A close-up image of a patient's small intestine with a protruding sac. This condition, called Meckel's diverticulum, is a congenital abnormality occurring in 2% of the population, usually males. *(Custom Medical Stock Photo, Inc.)*

There are three major complications that may result from the development of Meckel's diverticulum. The most common problem is inflammation or infection that mimics **appendicitis**. This diagnosis is defined at the time of surgery for suspected appendicitis. Bleeding caused by ectopic stomach tissue that results in a bleeding ulcer is the second most frequent problem. Bleeding may be brisk or massive. The third potential complication is obstruction due to **intussusception**, or a twist around a persistent connection to the abdominal wall. This problem presents as a small bowel obstruction, however, the true cause is identified at the time of surgical exploration.

Meckel's diverticulum is a developmental defect that is present in about 2% of people, but does not always cause symptoms. Meckel's diverticula (plural of diverticulum) are found twice as frequently in men as in women. Complications occur three to five times more frequently in males.

Causes and symptoms

Meckel's diverticulum is not hereditary. It is a vestigial remnant of the omphalomesenteric duct, an

WWW.BOOKBAZ.IR

KEY TERMS

Appendectomy—The procedure to surgically remove an appendix.

Appendicitis—Inflammation of the appendix.

Appendix—A portion of intestine attached to the cecum.

Cecum—The first part of the large bowel.

Congenital—Refers to a disorder that is present at birth.

Distal—Away from the point of origin.

Ectopic—Tissue found in an abnormal location.

Intussusception—One piece of bowel inside another, causing obstruction.

Isotope—Any of two or more species of atoms of a chemical element with the same atomic number and nearly identical chemical behavior but with differing atomic mass and physical properties.

Peptic ulcer—A wound in the bowel that can be caused by stomach acid or a bacterium called *Helicobacter pylori.*

Volvulus—A twisted loop of bowel, causing obstruction.

embryonic structure that becomes the intestine. As such, there is no genetic defect or abnormality.

Symptoms usually occur in children under 10 years of age. There may be bleeding from the rectum, **pain** and **vomiting**, or simply tiredness and weakness from unnoticed blood loss. It is common for a Meckel's diverticulum to be mistaken for the much more common disease appendicitis. If there is obstruction, the abdomen will distend and there will be cramping pain and vomiting.

Diagnosis

The situation may be so acute that surgery is needed on an emergency basis. This is often the case with bowel obstruction. With heavy bleeding or severe pain, whatever the cause, surgery is required. The finer points of diagnosis can be accomplished when the abdomen is open for inspection during a surgical procedure. This situation is called an acute abdomen.

If there is more time (not an emergency situation), the best way to diagnose Meckel's diverticulum is with a nuclear scan. A radioactive isotope injected into the bloodstream will accumulate at sites of bleeding or in stomach tissue. If a piece of stomach tissue or a pool of blood shows up in the lower intestine, Meckel's diverticulum is indicated.

Treatment

A Meckel's diverticulum that is causing discomfort, bleeding, or obstruction must be surgically removed. This procedure is very similar to an **appendectomy**.

Prognosis

The outcome after surgery is usually excellent. The source of bleeding, pain, or obstruction is removed so the symptoms also disappear. A Meckel's diverticulum will not return.

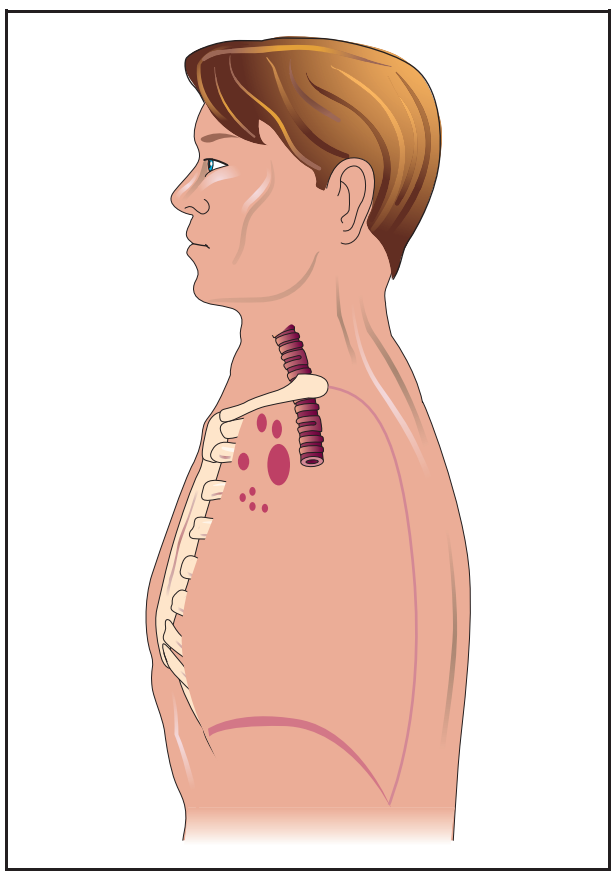
Mediastinoscopy

Definition

Mediastinoscopy is a surgical procedure that enables physicians to view areas of the mediastinum, the cavity behind the sternum (breastbone) that lies between the lungs. The organs in the mediastinum include the heart and its vessels; lymph nodes; and the trachea, esophagus, and thymus. Mediastinoscopy with biopsy is minor surgery for the removal of tissues from the mediastinum through very small incisions.

Purpose

Mediastinoscopy is most commonly used to detect or stage lung cancer, **mesothelioma**, or other cancers, such as **esophageal cancer**, and to determine whether the cancer has spread to the lymph nodes of the chest.



Mediastinoscopy is a surgical procedure used to detect or stage lymphoma or lung cancer. In this procedure, the surgeon makes an incision below the neck and inserts a mediastinoscope (a narrow, hollow tube with an attached light). *(Illustration by Electronic Illustrators Group. © Cengage Learning®.)*

It is also often the diagnostic method of choice for detecting lymphoma (cancer of lymphatic tissues), including Hodgkin's disease. Staging of lung and other cancers involves determining the level or progression of the cancer. Stages provide consistent definitions of cancer levels and may indicate the appropriate treatments. Staging also provides some guidance for prognosis. Mediastinoscopy and biopsy (tissue removal) from lymph nodes and other tissues or from abnormal growths in the front part of the mediastinum near the chest wall are likely to reveal whether a lung cancer has spread beyond the lungs. Mediastinoscopy is also useful for examining the outside surfaces of the airway tubes, such as the trachea, and for evaluating masses or tumors in the middle chest.

The lymph nodes between the lungs can also be biopsied during mediastinoscopy to check for infection. Mediastinoscopy is commonly performed on patients with enlarged lymph nodes to determine whether the enlargement is due to infection or a lung cancer that has spread to the nodes. Mediastinoscopy is used to detect infections such as **tuberculosis**, **sarcoidosis** (a chronic lung disease), and to confirm the diagnosis of certain other conditions and diseases of the respiratory organs, including **autoimmune disorders**.

Mediastinoscopy may be used to verify a diagnosis that was not confirmed by other methods, such as radiographic and laboratory studies. If a malignant tumor is confirmed during mediastinoscopy, the surgeon may immediately perform a surgical procedure to remove the tumor, combining the diagnostic and surgical procedures into one operation.

Demographics

Approximately 130,000 new pulmonary nodules are diagnosed each year in the United States, about half of which are malignant lung cancers. Many of these are diagnosed via mediastinoscopy.

Description

Mediastinoscopy is usually performed by a thoracic or general surgeon or a trained pulmonary specialist.

Mediastinoscopy is usually performed in a hospital operating room under general **anesthesia**. Before the general anesthesia is administered, local anesthesia is applied to the throat for the insertion of an endotracheal tube through the nose or mouth into the trachea. This enables the patient to breathe under general anesthesia while the head is tilted far back for the procedure. The tube keeps the throat open with the neck bent backward. A very small incision

KEY TERMS

Biopsy—The removal of cells or tissue for examination by a pathologist.

Cauterize—To use heat or chemicals to stop bleeding, prevent the spread of infection, or destroy tissue.

Endotracheal tube—A tube placed down the trachea (windpipe).

Hodgkin's disease—A malignancy of lymphoid tissue in the lymph nodes, spleen, liver, or bone marrow.

Lymph nodes—Small round structures located throughout the body that contain immune system cells for fighting infection.

Mediastinoscope—A thin hollow tube for performing mediastinoscopy.

Mediastinotomy—Surgical incision into the mediastinum.

Mediastinum—The space in the chest between the lungs that contains the heart and its vessels, lymph nodes, the trachea, esophagus, and thymus.

Mesothelioma—A tumor derived from mesothelial tissue such as the lining of the lungs, thorax, or perineum.

Pleural space—The space between the layers of the pleura—the membrane lining the lungs and thorax.

Positron emission tomography (PET)—A method of medical imaging capable of displaying the metabolic activity of organs.

Sarcoidosis—A chronic disease characterized by nodules in the lungs, skin, lymph nodes, and bones, although any tissue or organ in the body may be affected.

Thymus—An organ in the mediastinal cavity that is important for the body's immune response.

Ultrasound—An imaging method in which high-frequency sound waves are used to outline an internal region of the body.

of less than 1 in. (2.5 cm) is made, usually just below the neck or at the notch at the top of the sternum (breastbone) just above the clavicles. Carbon dioxide gas flows into the chest through this opening, and the lungs are allowed to collapse slightly, providing the surgeon with space to work. The soft tissue of the neck is dissected down to the trachea. The surgeon may clear a path to first feel the lymph nodes for any abnormalities. The surgeon then inserts the mediastinoscope, a type of endoscope, through the incision along the side of the trachea. The mediastinoscope is a narrow, hollow tube with an attached light and a camera that projects images of the organs inside the mediastinum onto a video screen. Tools can be inserted through the hollow tube of the mediastinoscope for performing biopsies. A tissue sample from the lymph nodes or a mass along the trachea or major bronchial tubes can be removed and examined under a microscope or sent to a laboratory for further testing.

Mediastinotomy is the surgical opening of the mediastinum and is complementary to mediastinoscopy. Mediastinotomy provides direct access to lymph nodes that are inaccessible by mediastinoscopy and, like mediastinoscopy, is used to evaluate or excise diseased lymph nodes and stage cancers. One or two small incisions, usually next to the sternum and between the ribs, enable the surgeon to insert additional instruments to cut out and remove lymph nodes. Other instruments are used to cauterize bleeding blood vessels with a small electric current. A **chest x ray** is usually taken after the procedure.

In some cases, if tissue sample analysis indicates a malignancy, surgery may be performed immediately, while the patient is already prepared and under anesthesia. In other cases, the surgeon will complete the visual study and biopsy, remove the instruments, reinflate the lungs, and stitch the small incisions closed. The patient will remain in the surgical recovery area until the effects of anesthesia have lessened, usually within a few minutes, and it is safe to leave the area. The entire procedure usually requires about 60–90 minutes, in addition to preparation and recovery time.

Mediastinoscopy is a safe, thorough, and cost-effective diagnostic tool that presents less risk than some other diagnostic procedures. However, **positron emission tomography** (PET) scanning has reduced the use of mediastinoscopy for staging cancers.

Precautions

Because mediastinoscopy is a surgical procedure, it should only be performed when the potential benefits outweigh the risks of anesthesia and surgery. Patients who had mediastinoscopy previously should not have it again if there is scarring from the first procedure. Several other medical conditions, such as impaired cerebral circulation, obstruction or distortion of the upper airway, or thoracic **aortic aneurysm** (abnormal dilation of the thoracic aorta) may also preclude mediastinoscopy. Certain structures in a person's anatomy that can be compressed by the mediastinoscope may complicate these pre-existing medical

conditions. Mediastinal irradiation is also a contraindication for mediastinoscopy.

Preparation

Mediastinoscopy is generally performed after other imaging tests, such as computed tomography (CT) scans, have suggested that a cancer may have spread to the lymph nodes between the lungs. The specific procedures of the mediastinoscopy are discussed with the patient. Patients also meet with their anesthesiologist to discuss their medical history and the anesthesia to be used. Patients sign a consent form after reviewing the risks of the procedure and the known risks and reactions to anesthesia. The physician will normally instruct the patient not to eat or drink anything after midnight before the test, until after the procedure is completed. This helps prevent nausea from the anesthesia. Patients should inform their physician of all medications they are currently taking, including **vitamins**, supplements, and over-the-counter drugs, as it may be necessary to stop or adjust dosages of any substances that affect blood clotting before undergoing mediastinoscopy. The physician may prescribe a sedative the night before and again immediately before the procedure. A local anesthetic is usually applied to the throat to prevent discomfort during placement of the endotracheal tube.

Aftercare

Following mediastinoscopy, patients are carefully monitored for any changes in vital signs or symptoms of complications from the procedure or anesthesia. The patient may have a **sore throat** from the endotracheal tube, experience temporary chest **pain**, and/or have soreness or tenderness at the incision site. Discomfort at the incision site(s) may last for a few days. Patients usually go home the same day, but must be driven since the medications will leave them drowsy for several hours. They should not drink alcohol for the rest of the day and should notify the doctor if **fever**, **shortness of breath**, or shoulder or chest pain develop. The patient will be left with a small straight scar of less than 1 in. (2.5 cm).

Risks

Complications from mediastinoscopy are relatively rare, although the usual risks associated with general anesthesia also apply to this procedure. Major and minor complications from general anesthesia occur in 3%–10% of all surgical patients. These are primarily heart and lung problems or infections. Complications from mediastinoscopy occur in less than 1% of patients. There is a risk of puncturing the esophagus, trachea, or blood vessels, which can lead to bleeding. The following complications, in decreasing order of frequency, have also been reported:

- pneumothorax—air in the pleural space, which can cause lung collapse but may be treated by inserting a drainage tube in the chest between the ribs for a few days
- vocal cord weakening or paralysis, causing hoarseness, due to recurrent laryngeal nerve injury
- infection
- tumor implantation in the wound
- injury to a thoracic nerve
- esophageal injury
- chylothorax—milky lymphatic fluid in the pleural space—from injury to a lymphatic duct
- air embolism (an air bubble)
- transient hemiparesis (paralysis on one side of the body)

Results

Mediastinoscopy biopsy results are generally available in five to seven days. Normal results of lymph node biopsies will indicate small, smooth lymph nodes with no abnormal tissue, growths, or signs of cancer or infection. Abnormal findings may indicate lung cancer, tuberculosis, sarcoidosis, lymphoma, Hodgkin's disease, or spread of disease from elsewhere in the body. In the case of lung cancer staging, the results indicate the severity and progression of the cancer. Mediastinoscopy with **lymph node biopsy** can indicate whether a cancer is localized or has begun to spread, which may affect treatment options. Mediastinoscopy can also be useful for distinguishing between lung cancer and mesothelioma, since lung cancers often spread to the lymph nodes, whereas mesothelioma spreads less often.

Mediastinoscopy results in a diagnosis in 10%–75% of cases, depending on the histology, location, and size of the cancer. However, the rate of false positives—diagnosing disease that is not present—can be as high as 20% with mediastinoscopy.

Morbidity and mortality rates

Morbidity from mediastinoscopy, such as bleeding, pain, or post-procedure infection, is relatively uncommon. Mortality is extremely rare.

WWW.BOOKBAZ.IR

Alternatives

Although mediastinoscopies continue to be performed, advancements in computed tomography (CT), **magnetic resonance imaging** (MRI), ultrasonography techniques, and PET scanning have led to a decline in its use. However, these less invasive techniques, especially **ultrasound**, are not as specific as mediastinoscopy and may not be as useful for diagnosis. Improved fine-needle aspiration (withdrawing fluid using suction) and core-needle biopsy (using a needle to obtain a small tissue sample) have reduced the need for mediastinoscopy and biopsy. New techniques in **thoracoscopy** (examination of the thoracic cavity with a lighted instrument called a thoracoscope) offer additional options for examining masses in the mediastinum. Mediastinoscopy may be required when other methods cannot be used or when the results from other methods are inconclusive.

Meditation

Definition

Meditation is a practice of concentrated focus upon a sound, object, visualization, the breath, movement, or attention itself in order to increase awareness of the present moment, reduce **stress**, promote relaxation, and enhance personal and spiritual growth.

Two people engaged in meditation. *(iofoto/Shutterstock.com.)*

Purpose

Meditation benefits people with or without acute medical illness or stress. People who meditate regularly have been shown to feel less **anxiety** and depression. They also report that they experience more enjoyment and appreciation of life and that their relationships with others are improved. Meditation produces a state of deep relaxation and a sense of balance or equanimity. Out of this experience of equanimity one may gain greater insight and understanding about one's thoughts, feelings, and actions. This insight in turn offers the possibility to feel more confident and in control of life. Meditation facilitates a greater sense of calmness, empathy, and acceptance of self and others.

Meditation can be used with other forms of medical treatment and is an important complementary therapy for both the treatment and prevention of many stress-related conditions. Regular meditation can reduce the number of symptoms experienced by patients with a wide range of illnesses and disorders. Based upon clinical evidence as well as theoretical understanding, meditation is considered to be one of the better therapies for **panic disorder**, **generalized anxiety disorder**, substance dependence and abuse, **ulcers**, **colitis**, chronic **pain**, **psoriasis**, and dysthymic disorder. It is considered to be a valuable adjunctive therapy for moderate **hypertension** (high blood pressure), prevention of cardiac arrest (**heart attack**), prevention of atherosclerosis (hardening of arteries), arthritis (including **fibromyalgia**), cancer, **insomnia**, migraine, and prevention of **stroke**. Meditation may also be a valuable complementary therapy for **allergies** and **asthma** because of the role stress plays in these conditions. Meditative practices have been reported to improve function or reduce symptoms in patients with some neurological disorders as well. These include people with Parkinson's disease, people who experience **fatigue** with **multiple sclerosis**, and people with **epilepsy** who are resistant to standard treatment.

Overall, a 1995 report to the National Institutes of Health on alternative medicine concluded that "More than 30 years of research, as well as the experience of a large and growing number of individuals and health care providers, suggests that meditation and similar forms of relaxation can lead to better health, higher quality of life, and lowered health care costs. . ."

Description

Origins

Meditation techniques have been practiced for millennia. Originally, they were intended to develop spiritual understanding, awareness, and direct experience of ultimate reality. The many different religious traditions in the world have given rise to a rich variety of meditative practices. These include the contemplative practices of Christian religious orders, the Buddhist practice of sitting meditation, and the whirling movements of the Sufi dervishes. Although meditation is an important spiritual practice in many religious and spiritual traditions, it can be practiced by anyone regardless of their religious or cultural background to relieve stress and pain.

As Western medical practitioners begin to understand the mind's role in health and disease, there has been more interest in the use of meditation in medicine. Meditative practices are increasingly offered in medical clinics and hospitals as a tool for improving health and quality of life. Meditation has been used as the primary therapy for treating certain diseases; as an additional therapy in a comprehensive treatment plan; and as a means of improving the quality of life of people with debilitating, chronic, or terminal illnesses.

Sitting meditation is generally done in an upright seated position, either in a chair or cross-legged on a cushion on the floor. The spine is straight yet relaxed. Sometimes the eyes are closed. Other times the eyes are open and gazing softly into the distance or at an object. Depending on the type of meditation, the meditator may be concentrating on the sensation of the movement of the breath, counting the breath, silently repeating a sound, chanting, visualizing an image, focusing awareness on the center of the body, opening to all sensory experiences including thoughts, or performing stylized ritual movements with the hands.

Movement meditation can be spontaneous and free-form or involve highly structured, choreographed, repetitive patterns. Movement meditation is particularly helpful for those people who find it difficult to remain still.

Generally speaking, there are two main types of meditation. These types are concentration meditation and mindfulness meditation. Concentration meditation practices involve focusing attention on a single object. Objects of meditation can include the breath, an inner or external image, a movement pattern (as in tai chi or **yoga**), or a sound, word, or phrase that is repeated silently (mantra). The purpose of concentrative practices is to learn to focus one's attention or develop concentration. When thoughts or emotions arise, the meditator gently directs the mind back to the original object of concentration.

MAHARISHI MAHESH YOGI (1911–2008)

Maharish Mahesh Yogi. *(AP Photo)*

Maharishi Mahesh Yogi was one of the most recognized spiritual leaders of the world. Almost single-handedly, the Maharishi (meaning great sage) brought Eastern culture into Western consciousness. He emerged in the late 1950s in London and the United States as a missionary in the cause of Hinduism, the philosophy of which is called Vedanta—a belief that "holds that God is to be found in every creature and object, that the purpose of human life is to realize the godliness in oneself and that religious truths are universal."

By 1967, the Maharishi became a leader among flower-children and an anti-drug advocate. The Maharishi's sudden popularity was helped along by such early fans as the Beatles, Mia Farrow, and Shirley MacLaine. These people, and many others, practiced Transcendental Meditation (TM), a Hindu-influenced procedure that endures in the United States in the early 2000s.

When the 1960s drew to a close, the Maharishi began to fade from public view. The guru still had enough followers, though, to people the Maharishi International University, founded in 1971. One of the main draws of Maharishi International University was the study of TM-Sidha, an exotic form of Transcendental Meditation. Sidhas believe that group meditation can elicit the maharishi effect—a force strong enough to conjure world peace.

In 1990, the Maharishi relocated his headquarters from Seelisberg, Switzerland, to a former Franciscan monastery in Vlodrop, Netherlands, where he continued his work in TM and tried to effect change in the world with peace. He died in 2008. More information about TM and the history of its credited founder can be found on http://www.tm.org/

Mindfulness meditation practices involve becoming aware of the entire field of attention. The meditator is instructed to be aware of all thoughts, feelings, perceptions or sensations as they arise in each moment. Mindfulness meditation practices are enhanced by the meditator's ability to focus and quiet the mind. Many meditation practices blend these two forms.

The study and application of meditation to health care has focused on three specific approaches: 1. transcendental meditation (TM); 2. The "relaxation response," a general approach to meditation developed by Dr. Herbert Benson; and 3. mindfulness meditation, specifically the program of mindfulness-based **stress reduction** (MBSR) developed by Jon Kabat-Zinn.

Transcendental meditation

TM has its origins in the Vedic tradition of India and was introduced to the West by Maharishi Mahesh Yogi. TM has been taught to somewhere between two and four million people. It is one of the most widely practiced forms of meditation in the West. TM has been studied many times; these studies have produced much of the information about the **physiology** of meditation. In TM, the meditator sits with closed eyes and concentrates on a single syllable or word (mantra) for 20 minutes at a time, twice a day. When thoughts or feelings arise, the attention is brought back to the mantra. According to Charles Alexander, an important TM researcher, "During TM, ordinary waking mental activity is said to settle down, until even the subtlest thought is transcended and a completely unified wholeness of awareness ... is experienced. In this silent, self-referential state of pure wakefulness, consciousness is fully awake to itself alone." TM supporters believe that TM practices are more beneficial than other meditation practices.

The relaxation response

The relaxation response involves a similar form of mental focusing. Herbert Benson, one of the first

Western doctors to conduct research on the effects of meditation, developed this approach after observing the profound health benefits of a state of bodily calm he calls "the relaxation response." In order to elicit this response in the body, he teaches patients to focus upon the repetition of a word, sound, prayer, phrase, or movement activity (including swimming, jogging, yoga, and even knitting) for 10–20 minutes at a time, twice a day. Patients are also taught not to pay attention to distracting thoughts and to return their focus to the original repetition. The choice of the focused repetition is up to the individual. Instead of Sanskrit terms, the meditator can choose what is personally meaningful, such as a phrase from a Christian or Jewish prayer.

Mindfulness meditation

Mindfulness meditation comes out of traditional Buddhist meditation practices. Psychologist Jon Kabat-Zinn has been instrumental in bringing this form of meditation into medical settings. In formal mindfulness practice, the meditator sits with eyes closed, focusing the attention on the sensations and movement of the breath for approximately 45–60 minutes at a time, at least once a day. Informal mindfulness practice involves bringing awareness to every activity in daily life. Wandering thoughts or distracting feelings are simply noticed without resisting or reacting to them. The essence of mindfulness meditation is not what one focuses on but rather the quality of awareness the meditator brings to each moment. According to Kabat-Zinn, "It is this investigative, discerning observation of whatever comes up in the present moment that is the hallmark of mindfulness and differentiates it most from other forms of meditation. The goal of mindfulness is for individuals to be more aware, more in touch with life and whatever is happening in their own body and mind at the time it is happening—that is, the present moment." The MBSR program consists of a series of classes involving meditation, movement, and group process. There are over 240 MBSR programs offered in healthcare settings around the world.

Meditation is not considered a medical procedure or intervention by most insurers. Many patients pay for meditation training themselves. Frequently, religious groups or meditation centers offer meditation instruction free of charge or for a nominal donation. Hospitals may offer MBSR classes at a reduced rate for their patients and a slightly higher rate for the general public.

Precautions

Meditation appears to be safe for most people. There are, however, case reports and studies noting some adverse effects. About 33% to 50% of the people participating in long silent meditation retreats (two weeks to three months) reported increased tension, anxiety, confusion, and depression. On the other hand, most of these same people also reported very positive effects from their meditation practice. Kabat-Zinn notes that these studies fail to differentiate between serious psychiatric disturbances and normal emotional mood swings. These studies do suggest, however, that meditation may not be recommended for people with psychotic disorders, severe depression, and other severe **personality disorders** unless they are also receiving psychological or medical treatment.

KEY TERMS

Dervish—A member of the Sufi order. Their practice of meditation involves whirling ecstatic dance.

Mantra—A sacred word or formula repeated over and over to concentrate the mind.

Transcendental meditation (TM)—A meditation technique based on Hindu practices that involves the repetition of a mantra.

Side effects

There are no reported side effects from meditation except for positive benefits.

Research and general acceptance

The scientific study of the physiological effects of meditation began in the early 1960s. These studies prove that meditation affects metabolism, the endocrine system, the central nervous system, and the autonomic nervous system. In one study, three advanced practitioners of Tibetan Buddhist meditation practices demonstrated the ability to increase "inner heat" as much as 61%. During a different meditative practice they were able to dramatically slow down the rate at which their bodies consumed oxygen. Preliminary research shows that mindfulness meditation is associated with increased levels of melatonin. These findings suggest a potential role for meditation in the treatment and prevention of breast and prostrate cancer.

Despite the inherent difficulties in designing research studies, there is a large amount of evidence of the medical benefits of meditation. Meditation is particularly effective as a treatment for chronic pain. Studies have shown meditation reduces symptoms of pain and pain-related drug use. In a four-year follow-up study, the majority

WWW.BOOKBAZ.IR

of patients in a MBSR program reported "moderate to great improvement" in pain as a result of participation in the program.

Meditation has long been recommended as a treatment for high blood pressure; however, there is a debate over the amount of benefit that meditation offers. Although most studies show a reduction in blood pressure with meditation, medication is still more effective at lowering high blood pressure.

Meditation may also be an effective treatment for **coronary artery disease**. A study of 21 patients practicing TM for eight months showed increases in their amount of **exercise** tolerance, amount of workload, and a delay in the onset of ST-segment depression. Meditation is also an important part of Dean Ornish's program, which has been proven to reverse coronary artery disease.

Research also suggests that meditation is effective in the treatment of chemical dependency. Gelderloos and others reviewed 24 studies and reported that all of them showed that TM is helpful in programs to stop **smoking** and also in programs for drug and alcohol abuse.

Studies also imply that meditation is helpful in reducing symptoms of anxiety and in treating anxiety-related disorders. Furthermore, a study in 1998 of 37 psoriasis patients showed that those practicing mindfulness meditation had more rapid clearing of their skin condition, with standard UV light treatment, than the control subjects. Another study found that meditation decreased the symptoms of fibromyalgia; over half of the patients reported significant improvement. Meditation was one of several stress management techniques used in a small study of HIV-positive men. The study showed improvements in the T-cell counts of the men, as well as in several psychological measures of well-being.

Mediterranean diet

Definition

The Mediterranean diet is better described as a nutritional model or pattern of food consumption rather than a diet in the usual sense of the word. To begin with, there is more than one Mediterranean diet, if the phrase is understood to refer to the traditional foods and eating patterns found in the countries bordering the Mediterranean Sea.

Description

Francesco Visioli, a researcher who has edited two books on the subject, prefers the term "Mediterranean diets" in the plural to reflect the fact that dietary habits differ within communities. For example, Visioli notes that alcohol intake is very low in the Maghreb area (coastal northwestern Africa) because most inhabitants of the region are Muslim, and, consequently, cereal grains figure more prominently in their diet than in most other Mediterranean countries. In addition, the differences among the various forms of the Mediterranean diet are important in understanding some of the research studies that have been done on it, as will be described more fully below.

Origins

The origins of the pattern of food consumption found in Mediterranean countries go back several millennia; descriptions of meals in ancient Greek and Roman literature would not be out of place in contemporary Mediterranean diet cookbooks. The first description of the traditional Mediterranean diet as it was followed in the mid-twentieth century, however, was not in a cookbook; it was in a research study funded by the Rockefeller Foundation and published in 1953. The author was Leland Allbaugh, who carried out a study of the island of Crete as an underdeveloped area. Allbaugh noted the heavy use of olive oil, whole-grain foods, fruits, fish, and vegetables in cooking, as well as the geography and other features of the island.

The Cretan version of the Mediterranean diet became the focus of medical research on the Mediterranean diet following the publication of Ancel Keys's

Mediterranean diet

Frequency	Food	Tips
Monthly	Red meats	No more than a few times month
Weekly	Sweets	Opt instead for naturally sweet fresh fruit
	Eggs	Less than 4 per week, including those in processed foods
	Poultry	A few times a week. Take the skin off and choose white meat to lower fat intake
	Fish	A few times a week
Daily	Cheese and yogurt	Cheese and yogurt are good sources of calcium. Choose low-fat varieties
	Olive oil	The beneficial health effects of olive oil are due to its high content of monounsaturated fats and antioxidants. Olive oil is high in calories, consume in moderation to reduce calorie intake
	Fruits	At least a serving at every meal. A serving of fruit is a healthy option for snacks
	Vegetables	At least a serving at every meal. Choose a variety of colors
	Beans, legumes, nuts	Beans are a healthy source of protein, and are loaded with soluble fiber, which has been shown to lower blood cholesterol levels by five percent or more. Most nuts contain monounsaturated (heart-healthy) fat. A handful of nuts is a healthy option for snacks
	Whole grains, including breads, pasta, rice, couscous, and polenta	A grain is considered whole when all three parts—bran, germ and endosperm—are present. Substitute whole wheat for white bread, brown rice for white rice and whole-wheat flour when baking. Mix pasta, rice, couscous, polenta and potatoes with vegetables and legumes
	Water	At least 6 glasses daily
	Wine (in moderation)	The U.S. Department of Agriculture defines moderation as no more than a five-ounce glass of wine daily for women and up to 2 glasses (10 ounces) daily for men
	Physical activity	Thirty minutes of cardiovascular activity a day is recommended to get in shape, burn calories and boost the metabolism

Seven Country Study in 1980. Keys (1904–2004) was a professor of **physiology** at the University of Minnesota and had a varied background in biology and **biochemistry** before turning to **nutrition**, almost by accident. Hired by the Army in 1941 to develop portable rations for troops in combat, Keys was responsible for creating what the Army then called K-rations.

His next wartime project was a **starvation** experiment, which he conducted in order to determine the food needs of starving civilians in war-torn Europe. U.S. soldiers who were trying to re-feed refugees in the newly liberated countries found that there was no reliable medical information about treating starvation victims. Keys recruited 36 healthy male volunteers in 1944 who were conscientious objectors, most of them from the historic peace churches. For five months the subjects were given half the normal calorie requirement of an adult male and asked to **exercise** regularly on a treadmill. The average weight loss was 25% of body weight. Three months after the experiment ended, Keys found that none of the subjects had regained their weight or physical capacity. He learned that re-nutrition following starvation requires several months of above-average calorie intake, that vitamin supplements are needed, and that the proportion of protein in the diet must be increased. He wrote a booklet with this information for use by relief agencies after the war ended.

In the process of studying the effects of starvation in European men who survived the war, however, Keys noticed that the rate of heart attacks among them dropped markedly as food supplies decreased. He wondered whether dietary factors might be involved in **heart disease**. A study of Minnesota businessmen and professors in the mid-1950s showed him that the fat content of food—particularly the saturated fats found in the meat and dairy products consumed in large amounts by Midwesterners—was indeed a factor. After that experiment, Keys began to think in terms of diet as preventive medicine. He first encountered Mediterranean **diets** during visits to Italy and Spain to conduct research for the World Health Organization (WHO). His studies of food consumption patterns in those countries eventually led to the Seven Countries Study, which was a systematic comparison of diet, risk factors for heart disease, and disease experience in men between the ages of 40 and 59 in 18 rural areas of Japan, Finland, Greece, Italy, the former Yugoslavia, the Netherlands, and the United States from 1958 to 1970. (Women were not included as subjects because of the rarity of heart attacks among them at that time and because the physical examinations were fairly invasive). In addition to asking the subjects to keep records of their food intake, the researchers performed chemical analyses of the foods the subjects ate. It was found that the men living on the island of Crete—the location of Leland

WWW.BOOKBAZ.IR

Allbaugh's 1953 study—had the lowest rate of heart attacks of any group of subjects in the study.

Subsequent studies of Mediterranean diets have been conducted in subjects who have already experienced heart attacks and in female subjects. One consistent finding of recent research is that people living in Mediterrean countries in the early twenty-first century are at higher risk of chronic diseases than participants of the late 1950s because the traditional diets of the Mediterranean region have been increasingly abandoned in favor of fast foods and higher consumption of fatty meat products and sweets, as well as other staples of North American and Northern European diets. In addition, changing agricultural practices around the Mediterranean have resulted in poultry and meat with higher fat content than was the case in the 1960s. As a result of concern about these trends, an association for the advancement of the Mediterranean diet was formed in Spain in 1995 and later funded the Foundation for the Advancement of the Mediterranean Diet, which is presently headquartered in Barcelona. The Foundation's objectives include publication and dissemination of scientific findings about the diet and the promotion of its healthful use among different population groups.

Mediterranean cuisine varies by region, but in general, Mediterranean diets have five major characteristics:

- High levels of fruits and vegetables, breads and other cereals, potatoes, beans, nuts, and seeds
- Olive oil as the principal or only source of fat in the diet
- Moderate amounts of dairy products, fish, and poultry; little use of red meat
- Wine consumed in moderate amounts—two glasses per day for men, one glass for women

Since wine and olive oil are obtained from their respective plant sources by physical (crushing or pressing) rather than chemical processes, their nutrients retain all the properties of their sources. Wine contains polyphenols, which are powerful **antioxidants** and also have a relaxing effect on blood vessels, thus lowering blood pressure.

The Mediterranean Diet Pyramid, which was updated in 2010, is an illustrated version of this typical dietary pattern. The base of the pyramid is labeled "Daily Physical Activity." Above this is the largest layer consisting of all plant foods: fruits, vegetables, seeds, nuts, grains, olives, and olive oil. The pyramid indicates that "this group should be the basis of most meals." Above this are fish and shellfish, which should be eaten at least twice a week. The fourth layer contains poultry, eggs, cheese, and yogurt that should be eaten in moderate portions daily to weekly. The smallest section of the pyramid is for red meat and sweets, to be eaten infrequently.

The Cretan version of the Mediterranean diet, as it was used on the island in the 1960s, was distinctive in several respects because it contained:

- A higher proportion of total calories from fat (40%), almost all of it from olive oil. It was low in animal fats (butter was rarely eaten) and saturated fats.
- A relatively low level of carbohydrate intake (45% of daily calories), with most of the carbohydrates coming from fruits (2–3 per day) and vegetables (2–3 cups per day), many of them foods with a low glycemic index. Vegetables are an integral part of meals in the Cretan diet; they are not considered side dishes.
- Generous portions of whole-grain bread (8 slices per day). The bread was made from slowly fermented dough, however, and had a lower glycemic index than most contemporary breads.
- Moderate intake of white and oily fish (about 40 grams per day), the latter which is rich in omega-3 fatty acids.
- A higher intake of meat than in most versions of the Mediterranean diet, mostly as lamb, chicken, or pork.
- High intake of alpha-linolenic acid (ALA; an omega-3 fatty acid thought to lower the risk of heart disease) from nuts (particularly walnuts), seeds, wild greens (particularly purslane [*Portulaca oleracea*]), and legumes. Lamb is also a good source of ALA.

Purpose

The purpose of Mediterranean diets as used in the United States and Western Europe is primarily preventive healthcare and secondarily as a means to weight loss. Several books are available with weight-loss regimens based on Mediterranean diets, as well as cookbooks with recipes from a variety of Mediterranean countries.

Most of the scientific research that has been done on Mediterranean diets concerns their role in preventing or lowering the risk of various diseases.

Mediterranean diets became popular in the 1980s largely because of their association with lowered risk of heart attacks and strokes, particularly in men, following the publication of the Seven Countries Study. Mediterranean diets are thought to protect against heart disease because of their high levels of **omega-3 fatty acids**, even though blood **cholesterol** levels are

not lowered. In 2010, a well-regarded twin study showed that the twin who ate a Mediterranean diet had better heart health than the identical twin who ate a standard American diet. The research cautioned, however, that the study looked only at white men and the results could not be generalized to women or other ethnic groups without additional research. A 2014 study looked at effects of the Mediterranean diet in firefighters who showed lower risk of metabolic syndrome and other risk factors for heart disease.

A study published in *Expert Review of Neurotherapeutics* in May 2011 found that higher adherence to a Mediterranean-type diet could be associated with slower cognitive decline, reduced risk of progression from mild cognitive impairment to Alzheimer's disease, reduced risk of Alzheimer's disease, and overall decreased risk of mortality in Alzheimer's disease patients. These findings suggested that adherence to the Mediterranean diet may affect not only the risk for Alzheimer's disease, but also for pre-dementia syndromes and their progression to overt **dementia**.

A group of researchers in Crete reported in 2007 that the low rate of **wheezing** and **allergic rhinitis** (runny nose) on the island may be related to the traditional Cretan diet. Children who had a high consumption of nuts, grapes, oranges, apples, and tomatoes (the main local products) were less likely to suffer from **asthma** or nasal **allergies**. Children who ate large amounts of margarine, however, were more likely to develop these conditions. Since this study, limited findings have shown this effect, but subsequent studies suggested that a high level of adherence to the Mediterranean diet early in life protects against the development of asthma and atopy in children. Further studies appear to confirm some of the effects. One study in 2013 showed that adhering to a Mediterranean diet lowered asthma symptoms in children, but mostly among children in the Mediterranean setting. Another 2013 study showed small but consistent improvement in breathing and quality of life for adults with asthma who followed the diet.

Research conducted at a clinic in Naples, Italy, suggests that Mediterranean diets lower the risk of developing or reversing the effects of metabolic syndrome, a condition associated with **insulin resistance** and an increased risk of heart disease, **obesity**, and type 2 diabetes. The results from this clinic were corroborated by a study done at Tufts University in Massachusetts, which found that the symptoms of metabolic syndrome were reduced even in patients who did not lose weight on the diet. These results have been confirmed by multiple well-designed studies.

Risks

There are no major risks associated with following a traditional Mediterranean diet for people who have consulted a physician beforehand if they intend to use the diet as a weight-loss regimen. Health crises caused by food interactions with **monoamine oxidase inhibitors** are uncommon, but can be fatal (about 90 deaths over a 40-year period). The risk of cancer or any other disease from aflatoxin-contaminated olive oil is minimal in the United States and Canada.

People who are making any major change in their dietary pattern in general should always consult their physician first. In addition, people who are taking monoamine oxidase inhibitors (MAOIs) for the treatment of depression should check with their doctor, as these drugs interact with a chemical called tyramine to cause sudden increases in blood pressure. Tyramine is found in red wines, particularly aged wines like Chianti, and in aged cheeses.

People using a Mediterranean diet for weight reduction should watch portion size and monitor their consumption of olive oil, cheese, and yogurt, which are high in calories. Dieters may wish to consider switching to low-fat cheeses and yogurts.

Because olive oil is a staple of Mediterranean diets, consumers should purchase it from reliable sources. The safety of olive oil is not ordinarily a concern in North America; however, samples of olive oils sold in Europe and North Africa are sometimes found to be contaminated by mycotoxins (toxins produced by molds and fungi that grow on olives and other fruits). Aflatoxin, a mycotoxin that has been found in olive oil, is a powerful carcinogen and has been implicated in **liver cancer**.

Research and general acceptance

Mediterranean diets have been the subject of more medical research since the 1960s than any other regional or ethnic diet. Interest in Mediterranean diets has been high because nutritional research in general has moved away from curing deficiency diseases in the direction of preventive health care. In general, the diets have received positive acceptance and results, but in 2014, the media made note of steadily rising obesity rates in Western Europe, which has led to some confusion and criticism of the diet. Most likely, the increased weight is attributable to the same causes as obesity in the United States, namely a more sedentary lifestyle and eating more fast or processed food.

WWW.BOOKBAZ.IR

The results from the Seven Countries Study were published in book form in 1980. The research teams found that Japanese and Greek men had far lower rates of cardiovascular disease than men from the other five other countries, with the Greek subjects from the island of Crete having the lowest rate of all. Although the study and 30 years of follow-up reports showed that the relationship among heart disease, body mass, weight, and obesity is complex, the Seven Countries research also showed that the type of fat in the diet is more important than the amount, and that the use of monounsaturated fats—particularly olive oil—is correlated with a lower risk of **heart attack** and **stroke**. The twenty-year follow-up report indicated that 81% of the difference in coronary deaths among the seven countries could be explained by differences in the average intake of saturated fatty acids.

The Lyon Diet Heart Study was the first clinical trial to demonstrate the beneficial effects of a Mediterranean-type diet. Begun in 1995, it was a major investigation of the effectiveness of a modified Cretan diet in preventing recurrent heart attacks. The subjects were a group of 605 Frenchmen under 70 years of age who had been treated in the previous six months for a heart attack. They were recruited from several hospitals in the area of Lyon, a city in east-central France. Half the subjects were given an hour-long educational introduction to a modified version of the Cretan diet (canola oil was substituted for olive oil) and advised to follow this Mediterranean-style diet. The other half (the control group) were given a prudent diet recommended by the American Heart Association (AHA). At the end of 4 years, overall death rates were 56% lower in the group that followed the modified Cretan diet.

Mediterranean diets continue to be fruitful subjects for medical investigators, partly because the countries where they originated are changing so rapidly, and partly because discussion continues as to which of the components of these diets is the most important in disease prevention. Although olive oil has been the focus of many studies, recent research done in Greece seems to indicate that the combination of the various foods and food groups in Mediterranean diets is what makes them so healthful, rather than any one specific component. This position is sometimes called the whole-diet approach.

In addition, other researchers are studying lifestyle factors other than food that may well contribute to the beneficial effects of Mediterranean cooking. These include a generally more relaxed attitude toward life; higher levels of physical activity (made possible in part by the warm sunny climate of the region); and the **fasting** practices of Greek Orthodox Christians, which lower fat intake and restrict the believer to a vegetarian diet for about 110 days out of every year.

In recent research, the Mediterranean diets appear to be more effective than low-fat diets in inducing clinically relevant long-term changes in cardiovascular risk factors and inflammatory markers. Some research looks promising, showing a high adherence to the Mediterranean diet is associated with slower cognitive decline, with reduced risk of mild cognitive impairment that progresses to Alzheimer's disease and with reduced risk of Alzheimer's disease, though the research is not conclusive. Previous observational studies already indicated that specific foods or nutrients found in traditional Mediterranean diets (e.g., fish, unsaturated fatty acids, antioxidant as **vitamin E**, vitamin B_{12}, folates, carotenes, flavonoids, moderate alcohol) may have potential protective effects against dementia or cognitive decline, and further studies will help in understanding if a benefit to following this diet and cognitive function occurs.

Some population studies carried out in Mediterranean countries (particularly Italy and Spain) have found that close adherence to a traditional Mediterranean diet is associated with lower weight and a lower **body mass index** (BMI). Meta-analysis of randomized controlled trials shows that the Mediterranean diet may be a useful tool to reduce body weight, especially when the Mediterranean diet is energy-restricted, associated with physical activity, and more than six months in length. A major reason for its effectiveness is the wide variety of enjoyable foods permitted on the diet combined with a rich tradition of ethnic recipes making use of these foods—which makes it easier and more pleasant for people to follow the diet for long periods of time.

Medullary sponge kidney

Definition

Medullary sponge kidney is a congenital defect of the kidneys where the kidneys fill with pools of urine.

Demographics

One in every 100 to 200 people have some form of this disease.

Description

The kidneys filter urine from the blood and direct it down tiny collecting tubes toward the ureters (ducts that carry urine from the kidney to the bladder). These tiny tubes gradually join together until they reach the renal pelvis, where the ureters begin. As the tubes join, they are supposed to get progressively bigger as they get fewer in number. In medullary sponge kidney, the tubes are irregular in diameter, forming pools of urine along the way. These pools encourage stone formation and infection.

Causes and symptoms

Although some cases of this disorder seem to be inherited, usually the cause is not known.

The symptoms associated with medullary sponge kidney are those related to infection and stone passage. Infection causes **fever**; back and flank **pain**; cloudy, frequent, and burning urine; and general discomfort. Stones cause pain in the flank or groin as they pass. They usually cause some bleeding. The bleeding may not be visible in the urine, but it is apparent under a microscope.

Diagnosis

Recurring kidney infections, bleeding, or stones will prompt x rays of the kidneys. The appearance of

KEY TERMS

Congenital—Present at birth.

Intravenous pyelogram—X rays of the upper urinary system using a contrast agent that is excreted by the kidneys into the urine.

Thiazide diuretic—A particular class of medication that encourages urine production.

Ureter—A tube that carries urine from the kidney to the bladder.

medullary sponge kidney on an intravenous pyelogram (x rays of the upper urinary system) is characteristic.

Treatment

Many people never have trouble with this disorder. For those that do, infections and stones require periodic treatment. Infections should be treated with **antibiotics** early in order to prevent kidney damage. Stones may need to be surgically removed. Often, removal can be accomplished without an incision but rather by reaching up with instruments through the lower urinary tract to grab the stones. This procedure is called a ureteroscopy. There is also a method of stone treatment called extracorporeal shock wave **lithotripsy** (ESWL). A special machine delivers a focused blast of shock waves that breaks stones into sand so that they will pass out naturally. It is considered reasonably safe and usually effective.

Prognosis

Ignoring symptoms can result in progressive damage to the kidneys and ultimate kidney failure, but attentive early treatment will preserve kidney function.

Prevention

Diligent monitoring for infection at regular intervals and at the first symptom will give the best long-term results. By drinking extra liquids, most stones can be prevented. The most common kind of stones, **calcium** stones, can be deterred by regularly taking a medication (thiazide diuretic) that encourages urine production.

Melanoma

Definition

Malignant melanoma is a type of cancer arising from the melanocyte cells of the skin. Melanocytes are cells in the skin that produce a pigment called melanin. Malignant melanoma develops when the melanocytes no longer respond to normal control mechanisms of cellular growth. They may then invade nearby structures or spread to other organs in the body (metastasis), where again they invade and compromise the function of that organ.

Description

Melanocytes are derived from a structure in the human embryo called the neural crest. They are distributed in the epidermis and thus are found throughout the skin. They produce a brown pigment known as melanin and are responsible for racial variations in

skin color, the color of **moles**, and **tanning** in response to sun exposure. Malignant degeneration of the melanocyte gives rise to the tumor known as melanoma, which has four subtypes. These are: 1) superficial spreading; 2) nodular; 3) lentigo maligna; and 4) acral lentiginous melanomas, accounting for 70%, 15% to 30%, 4% to 10%, and 2% to 8% of cases, respectively. Acral lentiginous melanoma, however, accounts for 35–60% of cases in dark-skinned people.

Malignant melanoma may develop anywhere on the body. In men, it is most common on the trunk. In women, it is most common on the back or legs. The subtype also may influence where the tumor develops; lentigo maligna is more common on the face, whereas acral lentiginous melanoma is more common on the palms of the hand, soles of the feet, or in the nail beds.

The locally invasive characteristic of this tumor involves vertical penetration of the malignant melanocytes through the skin and into the dermis and subcutis (the deepest layer of the skin that lies below the dermis). With the exception of the nodular variety of melanoma, there is often a phase of radial or lateral growth associated with these tumors. Since it is the vertical growth that characterizes the malignancy, the nodular variant of melanoma carries the worst prognosis. Fortunately, the superficial spreading type is the most common.

The primary tumor begins in the skin, often from the melanocytes of a preexisting mole. It is estimated that 50% to 70% develop spontaneously, whereas the remainder start in a preexisting mole. Once it becomes invasive, it may progress beyond the site of origin to the regional lymph nodes or travel to other organ systems in the body and become systemic in nature.

Lymph is the clear, protein-rich fluid that bathes the cells throughout the body. Lymph works its way back to the bloodstream via small channels known as lymphatics. Along the way, the lymph is filtered through cellular stations known as nodes; thus they are called lymph nodes. Nearly all organs in the body have a primary lymph node group filtering the tissue fluid, or lymph, that comes from that organ. Different areas of the skin have different primary nodal stations. For the leg, they are in the groin; for the arm, the armpit or axilla. For the face, it is the neck. Depending its location when it develops, the tumor may drain into one groin or armpit or both.

Cancer may also work its way into blood vessels as it invades deeper structures in its place of origin. If invasion of the blood vessels occurs, it provides yet another route for the cancer to spread to other organs of the body. When the cancer spreads elsewhere in the body, it has become systemic in extent, and the tumor growing elsewhere is known as a metastasis.

Untreated malignant melanoma follows a classic progression. It begins and grows locally, penetrating vertically. It may be carried via the lymph to the regional nodes, known as regional metastasis. It may move from the lymph to the bloodstream or penetrate blood vessels, directly allowing it to travel elsewhere in the body. When systemic disease or distant metastases occur, melanoma commonly involves the lung, brain, liver, or occasionally bone. The malignancy causes death when its uncontrolled growth compromises vital organ function.

Sun exposure definitely increases the risk of developing melanoma, particularly in older males. The melanocytes are part of the integument's photoprotective mechanism; in response to sunlight, they produce melanin that has a protective role from the sun's ultraviolet

WWW.BOOKBAZ.IR

rays. For Caucasians, the amount of melanin present in the skin is directly related to sun exposure. However, it is not so much the total sun exposure that seems important. The history of **sunburn**, especially if the burn was severe or occurred at an early age, correlates with the increased risk. On this basis populations of fair-skinned people living in areas of such high sun exposure as the southwest United States or Australia are subject to increased risk. Malignant melanoma also affects non-Caucasians—though sun exposure probably does not play a role—at a rate of 10% that of Caucasians. The most common form of melanoma in African Americans is acral lentiginous melanoma.

Frequent use of sunlamps, tanning beds, and tanning booths has been linked to the development of melanoma as well as other forms of **skin cancer**. Women who use tanning beds or booths more frequently than once per month are at greatest risk and are 55% more likely to develop malignant melanoma. Risk is greatest for individuals who are fair-skinned, who have blonde or red hair, and who have blue, green, or gray-colored eyes. People who burn easily after sun exposure; those who have previously been treated for skin cancer; and individuals with a family member diagnosed with skin cancer are at greater risk for the development of skin cancer after using tanning beds or booths. On May 29, 2014, the Food and Drug Administration (FDA) issued a formal warning about the use of sunlamps and similar indoor tanning devices, stating that they must carry warning labels regarding the increased risk of skin cancer associated with their use and that they should not be used by persons under the age of 18.

Demographics

According to the National Cancer Institute (NCI), 76,100 new cases of melanoma were likely to be diagnosed in the United States in 2014, about 43,890 in men and 32,210 in women, and 9,710 people would likely die from the disease, 6,470 men and 3,240 women. Unlike many cancers, which were declining in incidence as of 2014, the incidence of primary cutaneous malignant melanoma steadily increased between 1980 and 2014, possibly related to increase of sun exposure. As of 2014 the risk was about 13 per 100,000 of the population. Melanoma affects all age groups but is most commonly seen in patients between 30 and 60 years of age; the average age at time of diagnosis is 61. Nonetheless, the rate of melanoma was rising faster among young people than among older adults; as of 2014, melanoma was the most common cancer diagnosed in young adults between the ages of 25 and 29.

Causes and symptoms

The predisposing causes to the development of malignant melanoma are environmental and genetic. The environmental factor is excessive sun exposure. There are also genetically transmitted familial syndromes with alterations in the *CDKN2A* and *CDK4* genes, which encode for the tumor-suppressing proteins p16 and p19. In 2003 a group of Swedish researchers reported that 63 out of a group of 71 melanoma patients, or 89% of the group, had mutations in either the *NRAS* or the *BRAF* gene. The researchers found that these mutations occur at an early point in the development of melanoma and remain as the tumor progresses.

As of 2014, researchers thought there may be two pathways to malignant melanoma, one involving exposure to sunlight and the other with melanocyte proliferation triggered by other factors. This hypothesis is based on the difference in distribution of moles on the body between patients who develop melanomas on the face and neck and those who develop melanomas on the trunk or legs. A small percentage of melanomas arise within burn scar tissue. Researchers do not fully understand the relationship between deep **burns** and an increased risk of skin cancer.

Melanin production in fair-skinned people is induced by sun exposure. An exposure substantial enough to result in mild sunburn will be followed by melanin producing a tan that may last a few weeks. Both ultraviolet radiation and damaging oxygen radicals caused by sun exposure may damage cells, particularly their DNA. It is suspected that this damage induces mutations that result in the development of malignant melanoma. Though these mutations are alterations of the genome causing the melanoma, they are environmentally induced and account for sporadic or spontaneous cases of this disease.

A rare inherited condition known as xeroderma pigmentosum (XP) increases a person's risk of malignant melanoma. People with XP lack an enzyme that is needed to repair damage caused by sunlight to the DNA in skin cells. Without this protective enzyme, the DNA in individual skin cells can undergo mutations leading to melanoma and other types of skin cancer. Fewer than 40% of individuals with XP survive beyond the age of 20.

A positive family history of one or two first-degree relatives having had melanoma substantially increases the risk on a genetic basis. A family tendency is observed in 8% to 12% of patients. The syndrome known as the dysplastic (atypical) nevus syndrome is characterized by atypical moles with bothersome

clinical features in children under age ten. Such individuals have to be observed closely for the development of malignant melanoma. Chromosome 9p has been identified as being involved in a familial predisposition. There are mutations in up to 50% of familial melanoma patients of the tumor-suppressing gene *CDKN2A*. The actual number of moles increases risk, but the size of the moles needs be considered. Those with ten larger moles of over 1 cm (0.4 in.) are at greater risk than those with a higher number (50–99) of smaller moles. Finally, when a child is born with a large congenital mole, careful observation for change is appropriate because of increased risk.

An excellent way of identifying changes of significance in a mole is the ABCDE rule:

- Asymmetry. A normal mole is round, whereas a suspicious mole is unevenly shaped.
- Border. A normal mole has a clear-cut border with the surrounding skin, whereas the edges of a suspect mole are often irregular or scalloped.
- Color variegation. Normal moles are uniformly tan or brown, but cancerous moles may appear as mixtures of red, white, blue, brown, purple, or black.
- Diameter greater than 6 mm (0.24 in.). Normal moles are usually less than 5 millimeters in diameter. A skin lesion greater than one-fourth inch across (about the size of a pencil eraser) may be suspected as cancerous.
- Evolution. A mole that changes over time in color or shape or develops itchiness or bleeding can be suspect.

Note that four of the criteria refer to variability of the lesion (color variegation refers to areas of light color and black scattered within the mole). Thus small uniform regular lesions are less cause for concern. It is important to realize that change in a mole or the rapid development of a new one are very important symptoms.

Another summary of important changes in a mole is the Glasgow 7-point scale. The symptoms and signs below can occur anywhere on the skin, including the palms of the hands, soles of the feet, and nail beds:

- change in size
- change in shape
- change in color
- inflammation
- crusting and bleeding
- sensory change
- diameter greater than 7 mm (0.28 in.)

In this scheme, change is emphasized along with size. Bleeding and sensory changes are relatively late symptoms.

Symptoms related to the presence of regional disease are mostly those of nodules or lumps in the areas containing the lymph nodes draining the area. Thus nodularity can be found in the armpit, the groin, or the neck if regional nodes are involved. There is also a special type of metastasis that can occur regionally with malignant melanoma; it is known as an in-transit metastasis. If the melanoma is spreading through the lymph system, some of the tumor may grow there, resulting in a nodule part way between the primary site and the original lymph node. These in-transit metastases are seen both at the time of original presentation or later after primary treatment has been rendered, the latter being a type of recurrence.

Finally, in those who either have upon first examination or progress to widespread or systemic disease, symptoms and signs are related to the affected organ. Thus neurological problems, lung problems, or liver problems develop depending on the organ involved.

Diagnosis

The clinical signs or symptoms discussed above are not absolute indications that a patient has malignant melanoma. The actual diagnosis is accomplished by biopsy, a procedure that removes tissue to examine under a microscope. It is important that the signs and symptoms are used to develop a suspicion of the diagnosis because the way the biopsy is performed for melanoma may be different than for other lesions of the skin.

The doctor may also use a dermatoscope to examine the mole prior to removal. The dermatoscope, which can be used to distinguish between benign moles and melanomas, resembles an ophthalmoscope; it has a light source attached and magnifies the details of the skin lesion. An immersion oil is first applied to the mole to make the outer layers of skin transparent.

In treating an early malignant melanoma, it is important to establish the exact thickness of penetration of the primary tumor. Any biopsy that does not remove the full vertical extent of the primary is inadequate. Therefore, if a skin lesion is suspicious, full-thickness excisional biopsy is the approach recommended. Shave biopsies and biopsies that remove only a portion of the suspect area are inappropriate. Often, in an early case, the excision involves just the suspicious lesion with minimal normal skin, but it should be a full vertical excision of the skin. Early-stage melanomas can be excised by Mohs surgery, a

WWW.BOOKBAZ.IR

technique that involves removal of the visible melanoma followed by removal of skin that may contain cancer cells one layer at a time. The surgeon examines each layer of skin under a microscope before proceeding to the next layer. When no more cancer cells are found, the Mohs surgery is complete. The Mohs approach, which is also called micrographic surgery, has a very high cure rate.

If a melanoma is diagnosed, further treatment of this area will often be necessary but does not compromise outcome (prognosis). In some special areas of the body, minor modifications may be necessary about initial total excision, but full-thickness excision should always be the goal. Once the diagnosis is obtained, careful examination of the patient for regional lymph node involvement should be done. A careful review to uncover any symptoms of widespread disease is also appropriate.

Most patients have an early melanoma, and extensive testing is not usually warranted. Routine testing in this situation involves a **complete blood count**, a chest x ray, and determinations of blood enzymes, including lactic dehydrogenase and alkaline phosphatase. If the patient has signs or symptoms of more advanced disease or if the lesion's depth of penetration is sizeable, further imaging studies may be appropriate. These would involve CAT scans of the abdomen, the chest, or regional nodal areas, or a CT or MRI of the brain. A **positron emission tomography** (PET) scan may also be used to look for melanoma metastases. PET scans involve the use of radioactive glucose to look for cancer cells, as cancers take up sugar more rapidly than normal tissues.

Treatment

The key to successful treatment is early diagnosis. Patients identified with localized, thin, small lesions (typified by the superficial spreading subtype) nearly always survive. For those with advanced lesions, the outcome is poor in spite of progress in systemic therapy.

Clinical staging

Malignant melanoma is locally staged based on the depth of penetration through the skin and its appendages. There are two ways of looking at the depth of penetration. The Clarke system utilizes the layers of the dermis and the skin appendages present at that layer to identify the depth of penetration. The Breslow system uses the absolute measurement of depth. Though useful conceptually, the Clarke system is used less frequently because of the fact that skin is of different thickness in different regions of the body. The depth of penetration is much greater when the tumor reaches the subcutaneous fat when the skin involved is the back as opposed to the face. It turns out that the Breslow measurement is more reproducible and thus more useful; therefore, for purposes here, depth of penetration by absolute measurement (Breslow) is used in local staging.

These stages are subdivided on the basis of penetration. Stage Ia is 0.75 mm or less (1 mm = 0.04 in.), and Stage Ib is 0.75–1.5 mm penetration. Stage IIa is 1.5–4.0 mm and Stage IIb is over 4.0 mm or into the subcutaneous fat. In stage III and IV, there is disease beyond the primary site. Stage III is defined by the presence of in-transit or regional nodal metastasis or both. Stage IV is defined by the presence of distant metastases.

Once the diagnosis of malignant melanoma has been established by biopsy and the stage has been identified using the results of the examination and studies, a treatment plan is developed. Melanoma is not cured unless it is diagnosed at a stage when it can be isolated and removed surgically. Considerations revolve around the extent of the local and regional nodal surgery for stages I through III. For stage IV patients, or those that are treated and then develop recurrence at distant sites, **chemotherapy** or immunotherapy is planned. Adjuvant therapy (auxiliary drug treatment used to make possibility of relapse less for those at high risk) is also considered.

Surgical therapy for the primary site is that of wide local removal of the skin, including subcutaneous tissue surrounding the lesion. In the past, wide excisions were large and encompassed 2 inches of tissue in all directions wherever feasible. It has been shown that such wide local excisions are not necessary. The question became how wide is enough. Studies from the World Health Organization Melanoma Group and by the Melanoma Intergroup Committee in the United States provided general guidelines based on the depth of penetration of the melanoma. These guidelines and anatomic considerations need to be kept in mind by the surgeon.

The next issue in primary management is whether the patient should have the regional lymph nodes removed in addition to treatment of the primary tumor. The problems associated with the resection of regional lymph nodes are those of lifelong **edema** or swelling in the extremity. Though it does not occur in all patients (5%–20%, depending on the extremity and extent of the dissection), it can be a disabling symptom. Certainly, if it could be ascertained that there was

disease in the nodes, resection (removal) would be appropriate. However, if there was no disease, the risk of edema should be avoided. In patients with no signs of regional disease, depth of penetration of the primary tumor helps guide the decision. If the tumor penetrates less than 1mm, dissection is not usually done. If it is 1–2 mm, node dissection may be done at the time of primary treatment, or the patient may be observed and undergo lymph node dissection only if the area later shows signs of disease. If the patient has enlarged lymph nodes or the depth of the tumor has led to the evaluation by CAT scan showing enlarged nodes, resection of the nodes is considered. In the latter case, more extensive imaging of the lung, liver, or brain may be appropriate to be sure the patient does not already have stage IV disease.

Questions related to which patients should have resection of regional lymph nodes have led to an intermediary procedure known as sentinel node mapping and biopsy. Intermediate thickness melanomas between 1 and 4 mm deep (0.04 and 0.16 in.) may have nodal involvement even if the examination and any other studies done are normal. If a radioisotope tracer or blue dye is injected into the area of the primary tumor, very shortly it will travel to the lymph nodes draining that area. These sentinel nodes are thus identifiable and are the most likely to harbor any regional metastatic disease. If these nodes alone are biopsied and are normal, the rest of the lymph node group can be spared. If they show microscopic deposits of tumor, then the full resection of the lymph node group may be completed. This procedure allows selection of those patients with intermediate thickness melanoma who will benefit from the regional lymph node dissection.

Patients with metastatic melanoma who do not respond well to other therapies may be candidates for treatment with aldesleukin. Aldesleukin is a form of interleukin, a specific kind of biological response modifier that promotes the development of T-cells. These cells are part of the lymphatic system and can directly interact with and fight cancer cells. Although aldesleukin is produced naturally in the body, its therapeutic form is developed via biotechnology in a laboratory setting. Treatment is considered palliative, which means that it provides comfort but does not produce a cure. Side effects, however, can be severe and range from flu-like symptoms to whole-body infection (**sepsis**) and **coma**.

Some patients, such as those with IIb or stage III melanoma, are at high risk for the development of recurrence after treatment. Although these patients are clinically free of disease after undergoing primary treatment, they are more likely to have some microscopic disease in the body that studies have not yet been able to identify. In an effort to decrease the rate of relapse, adjuvant therapy may be considered. Interferon alpha 2a is an agent that stimulates the immune system. This adjuvant therapy may slightly increase the duration of a patient's disease-free state and lengthen overall survival. However, interferon alpha 2a has high toxicity, and patients may not tolerate the side effects. Another drug used in immunotherapy for advanced-stage melanoma is ipilimumab, a synthetic version of an immune system antibody. Still another option is Bacille Calmette-Guérin (BCG) vaccine, which also stimulates the immune system.

A newer type of treatment for advanced-stage melanoma is targeted therapy. Targeted therapy is a type of drug therapy that blocks the growth of skin cancers by interfering with signaling pathways or specific molecules that the cancer cells need for growth. There were several types of targeted therapy drugs used as of 2014. One group targets cells with mutations in the *BRAF* gene; it included drugs such as vemurafenib and dabrafenib, which attack the BRAF protein directly and shrink metastatic tumors, thus prolonging the patient's survival time. Some acral melanomas contain mutations in the *C-KIT* gene; they may respond to treatment with imatinib or nilotinib, drugs that are known to affect cells with *C-KIT* mutations.

Unfortunately, treatment for those patients who already have or go on to develop systemic disease usually fails; melanoma that has metastasized to the brain is particularly difficult to treat. The chemotherapeutic agent dacarbazine, or DTIC, seems to be the most active agent. Overall responses have been noted in about 20% of patients, and they last only two to six months. Combination therapy may be an option. The regimen of DTIC + BCNU (carmustine) plus cisplatin plus tamoxifen delivers a response rate of 40%. Combining such biologic or immunologic agents as interferon with standard chemotherapeutic agents has been studied and shown improved response rates, though toxicity is substantial and only healthier, younger patients tolerate the treatment.

Some researchers have investigated the reasons why melanomas are so resistant to chemotherapy. One suggestion is that the genes ordinarily responsible for apoptosis (cell self-destruction) do not function normally in melanomas. The development of new drugs to treat melanoma depends on a better understanding of the complex processes involved in apoptosis.

KEY TERMS

Adjuvant therapy—Treatment given to patients who are at risk of having microscopic untreated disease present but have no obvious symptoms.

Dermis—The deeper portion or layer of the skin beneath the epidermis.

Dysplastic nevus syndrome—A familial syndrome characterized by the presence of multiple atypical appearing moles, often at a young age.

Epidermis—The uppermost layer of skin cells.

Genome—The genetic makeup of a cell, composed of DNA.

Immunotherapy—A form of treatment that uses biologic agents to enhance or stimulate normal immune function.

Integument—The medical name for the skin.

Lymph node dissection—Surgical removal of a group of lymph nodes.

Lymphedema—Swelling of an arm or leg following surgical removal of the lymph nodes that drain the limb.

Melanocytes—Skin cells derived from the neural crest that produce the protein pigment melanin.

Metastasis (pl. metastases)—A tumor growth or deposit that has spread via lymph or blood to an area of the body remote from the primary tumor.

Mohs surgery—A form of microscopically controlled surgery that allows for the precise removal of cancerous tissue. It is commonly used to treat various types of skin cancer, particularly in areas of the body where preserving as much tissue as possible is essential. Mohs surgery is also known as micrographic surgery.

Nevus (pl. nevi)—A medical term for mole.

Resection—The act of removing something surgically.

Skin appendages—Structures related to the integument such as hair follicles and sweat glands.

Subcutis—The deepest layer of skin tissue that lies below the dermis.

Targeted therapy—In cancer treatment, a type of drug therapy that blocks tumors by interfering with signaling pathways or specific molecules that the cancer cells need for growth. Also called biologic therapy, targeted therapy is less harmful to normal cells than traditional chemotherapy.

Variegation—Patchy variation in color.

Xeroderma pigmentosum (XP)—A rare inherited skin disorder in which the skin cells lack an enzyme needed to repair damage to the cell's DNA caused by sunlight. People with XP are 1,000 times more likely to develop melanoma than people without the disorder.

Though **radiation therapy** has a minimal role in the primary treatment of malignant melanoma, for patients who have metastatic disease, radiation may be helpful. This is true in patients who have developed tumor deposits in such areas as the brain or bone. Therapy that is intended to relieve the symptoms of the disease rather than cure it is called palliative therapy.

Prognosis

Almost all patients survive stage Ia malignant melanoma, and the survivorship for stage I overall is 92–97%. Survival drops in stage IIa to about 70% at five years and is worse yet for stage IIb at slightly over 50%. Stage III has a survival rate at 5 years of 40%, depending on the size and number of regional nodes involved. Stage IV malignant melanoma has a 5-year survival rate of about 10–15%.

Coping with cancer treatment

For those with familial tendencies for malignant melanoma, **genetic counseling** may be appropriate. Psychological counseling may be appropriate for anyone having trouble coping with a potentially fatal disease. Local cancer support groups may be helpful and are often identified by contacting local hospitals or the American Cancer Society.

Prevention

There are many interventions to decrease the risk of skin cancer:

- Protective clothing (long sleeves, sunglasses, and hat) should be worn while people are in the sun. Some companies make clothing that is more tightly woven and is coated with special products to block UV radiation.

- People should use sunscreen of at least 15 SPF when outside. Sunscreens as high as 100 SPF are available. SPF 15 sunscreens filter out about 93% of UVB rays; SPF 30 sunscreens filter out about 97%; SPF 50 sunscreens about 98%; and SPF 100 sunscreens about 99%. They should check the expiration date on sunscreen products; most are good for two to three years.
- It is wise to avoid being outside when the sun is brightest, between 10 A.M. and 4 P.M..
- The use of sunlamps and tanning beds and booths should be avoided. Legislation was proposed in several states as of 2014 to prohibit minors from visiting tanning salons.
- Children need special protection against the sun as their skin burns more easily, they spend more time outdoors than most adults, and they are less knowledgeable about the dangers of too much sun. Babies younger than six months should be kept out of direct sunlight.
- People should remember that UV rays can be reflected from the surface of the ocean, sandy beaches, or snow-covered ski slopes. It is a good idea to check the local weather forecast for the UV index for the day before heading outdoors.
- People should check their skin periodically for abnormal moles. The American Academy of Dermatology recommends people do this on their birthday: Although self-examination does not prevent skin cancer, early detection improves prognosis. The American Cancer Society PDF on prevention and early detection includes a detailed description of self-examination of the skin.

Although melanoma has been linked to mutations in several specific genes as of 2014, **genetic testing** was not recommended as a preventive strategy, even when several members of a family have been diagnosed with the disease. Regular skin examinations by a dermatologist and periodic self-examination are more useful in detecting early-stage melanoma.

Melioidosis

Definition

Melioidosis is an **infectious disease** of humans and animals caused by a gram-negative bacillus found in soil and water. It has both acute and chronic forms.

Description

Melioidosis, which is sometimes called *Pseudomonas pseudomallei* infection, is endemic (occurring naturally and consistently) in Southeast Asia, Australia, and parts of Africa. It was rare in the United States prior to early twenty-first-century immigration from Southeast Asia. Melioidosis is presently a **public health** concern because it is most common in **AIDS** patients and intravenous drug users.

Causes and symptoms

Melioidosis is caused by *Pseudomonas pseudomallei,* a bacillus that can cause disease in sheep, goats, pigs, horses, and other animals, as well as in humans. The organism enters the body through skin abrasions, **burns**, or **wounds** infected by contaminated soil; inhalation of dust; or by eating food contaminated with *P. pseudomallei*. Person-to-person transmission is unusual. Drug addicts acquire the disease from shared needles. The incubation period is two to three days.

Chronic melioidosis is characterized by **osteomyelitis** (inflammation of the bone) and pus-filled abscesses in the skin, lungs, or other organs. Acute melioidosis takes one of three forms: a localized skin infection that may spread to nearby lymph nodes; an infection of the lungs associated with high **fever** (102°F/38.9°C), **headache**, chest **pain**, and coughing; and septicemia (blood **poisoning**) characterized by disorientation, difficulty breathing, severe headache, and an eruption of pimples on the head or trunk. The third form is most common among drug addicts and may be rapidly fatal.

Diagnosis

Melioidosis is usually suspected based on the patient's history, especially travel, occupational exposure to infected animals, or a history of intravenous drug. Diagnosis must then be confirmed through laboratory tests. *P. pseudomallei* can be cultured from samples of the patient's sputum, blood, or tissue fluid from abscesses. Blood tests, including complement fixation (CF) tests and hemagglutination tests, also help to confirm the diagnosis. In acute infections, chest x rays and **liver function tests** are usually abnormal.

Treatment

Patients with mild or moderate infections are given a course of trimethoprim-sulfamethoxazole (TMP/SMX) and ceftazidime by mouth. Patients with acute melioidosis are given a lengthy course of ceftazidime followed by TMP/SMX. In patients with acute septicemia, a combination of **antibiotics** is administered intravenously, usually tetracycline, chloramphenicol, and TMP/SMX.

Prognosis

The mortality rate in acute cases of pulmonary melioidosis is about 10%; the mortality rate for the septicemic form is significantly higher (slightly above

50%). The prognosis for recovery from mild infections is excellent.

Prevention

There is no form of immunization for melioidosis. Prevention requires prompt cleansing of scrapes, burns, or other open wounds in areas where the disease is common and avoidance of needle sharing among drug addicts.

Memory loss

Definition

Memory loss is the inability to recall past events or knowledge. It is also called forgetfulness, **amnesia**, impaired memory, and loss of memory. Forgetfulness is generally mild and is experienced by almost everyone during life. Amnesia is total loss of memories, such as name and personal history.

Description

Mild memory loss, such as the inability to recall someone's name or where an item was last placed (such as keys or eyeglasses), occurs in adults of all ages. It usually becomes more frequent as a person ages. Mild memory loss is referred to as forgetfulness. Mild cognitive impairment (MCI) or impaired memory is considered a transitional state between normal forgetfulness and severe memory loss. At least one cognitive (thinking) function, usually memory, is below normal or declining. When memory is affected, the condition is called amnesic MCI. Although some people with MCI remain stable or even improve, studies show that the majority, especially those with amnesic MCI, eventually develop **dementia**.

Severe memory loss is memory impairment to such a degree that it affects a person's ability to do everyday activities, such as driving, handling finances, or shopping. Severe memory loss includes dementia and Alzheimer's disease.

There is a big difference between mild and severe forgetfulness. Mild forgetfulness is more common as people age. It may take longer for older people to learn new information, remember familiar names or words, or where they last placed commonly used objects. These are usually signs of mild forgetfulness and not serious memory loss problems. The most common types of severe memory loss are dementia and Alzheimer's disease.

Dementia

Dementia is a descriptive term for a collection of symptoms caused by a number of disorders affecting the brain. People with dementia have significantly impaired intellectual functioning that interferes with normal activities and relationships. They lose their ability to solve problems and maintain emotional control, and they may experience personality changes and behavioral problems, such as agitation, **delusions**, and **hallucinations**. While memory loss is a common symptom of dementia, memory loss by itself does not mean that a person has dementia.

Dementia is a condition almost always associated with the elderly. Doctors diagnose dementia only if two or more brain functions—such as memory and language skills—are significantly impaired without loss of consciousness. There are different types of dementia, including Alzheimer's disease (AD), Pick disease, frontal lobe dementia, multi-infarct dementia, and dementia caused by an **infectious disease**, usually human **immunodeficiency** virus (HIV). AD is the most common type of dementia.

Alzheimer's disease

Alzheimer's disease (AD) is an illness of the brain and is a type of dementia. AD causes changes in the brain tissue, including abnormal clumps (amyloid plaques) and tangled bundles of fibers (neurofibrillary

WWW.BOOKBAZ.IR

tangles). Excessive amounts of these plaques and tangles in the brain are considered signs of AD. Onset of AD usually begins after age 60 and nearly half of people age 85 and older may be affected. Although it is not a normal part of **aging**, AD is a disorder that, with almost no exceptions, affects older people and progresses as the person ages. There is no cure and only limited treatments are available.

The cause of AD is unknown, but the suspicion is the condition is caused by multiple factors. In addition to formation of amyloid plaques and neurofibrillary tangles, researchers have found other brain changes in people with AD. Nerve cells die in areas of the brain that are vital to memory and other mental abilities, and connections between nerve cells are disrupted. There are lower levels of some of the chemicals in the brain that carry messages back and forth between nerve cells. AD may impair thinking and memory by disrupting these messages.

Genetics also plays a role in disease development. AD is a genetic disease, meaning it is inherited and may affect several members in a family. The extent genetic factors play in developing AD remains unclear. Some studies indicate more than half of people with AD inherited it in their genetic profile. Other studies indicate only 25% of AD cases are inherited. Non inherited AD is referred to as sporadic Alzheimer's disease. By 2007, researchers had discovered three genes that can cause early-onset AD when mutated, and two genes that increase the risk for late-onset AD (one of which is the SORL 1 gene).

AD often starts slowly. People with AD often blame their forgetfulness on old age. Over time, their memory problems worsen and they lose the ability to drive a car, cook a meal, or even read a newspaper. They may get lost easily and find even simple tasks confusing. Some people become worried, angry, or violent. At some point, people with advanced AD may need someone to take care of all their needs, including feeding, bathing, and grooming, either at home or in a nursing home.

Demographics

No statistics are kept on mild memory loss since it is considered a minor inconvenience that nearly everyone experiences, especially as they grow older. The same is true for MCI, since there is no medical consensus on its definition. Accurate figures are also difficult to obtain because not everyone with a decline of memory shows symptoms.

As of 2007, the U. S. Congress' Office of Technology Assessment estimated that up to 6.8 million people in the United States had dementia, and at least 1.8 million of those were severely affected. Studies have found that almost half of all people age 85 and older have some form of dementia. Dementia usually begins after age 60, and the risk increases with age. At least 5% of men and women ages 65–74 have dementia.

The Alzheimer's Association estimates 5.1 million Americans have AD. By 2050 the number could rise to 13.2 million, according to the American Health Assistance Foundation (AHAF). The exact number is difficult to determine since AD is often misdiagnosed as another condition or is not diagnosed until the disease is in its later stages. The AHAF reports that approximately 65,800 people die from complication related to AD, and 350,000 new cases of AD are diagnosed each year in the United States. Worldwide, AHAF estimates 26 million people have AD as of 2007 and projects that number will increase to 106 million by 2050.

Causes and symptoms

Causes of memory loss besides the normal forgetfulness associated with aging include:

- side effects of medication
- dementia, Alzheimer's disease, and other degenerative nerve disorders of the brain

Possible causes of reversible memory loss

- **Alcoholism:** Abuse of alcohol can severely impair a person's mental abilities and may cause memory loss by interacting with medications.
- **Depression or other mental health disorder:** Stress, anxiety, or depression can trigger temporary memory loss, especially in older people. mWhen the stress is diminished, the symptoms disappear.
- **Medications:** Single medications or certain drug interactions may produce side effects or symptoms that mimic Alzheimer's disease. Specific medications include pain relievers, blood pressure medications, and sedatives.
- **Minor head trauma or injuries:** Falls or other head injuries may cause a loss of consciousness, with the victim having no recollection of the incident. Patients should see a doctor if they find an unexplained lump on the head or feel mentally fuzzy after even a minor fall.
- **Vitamin B-12 deficiency:** Vitamin B-12 helps to maintain healthy nerve and red blood cells. A deficiency, particularly common in older adults, may result in memory loss.

All forms of dementia result from the death of nerve cells and/or the loss of communication among these cells.

Diagnosis

Mild memory loss

Without using formal tests it may be possible to get an idea of cognitive function by discussing current events with the patient. A physician may ask patients if they read the newspapers or watch the news on television. If so, the physician questions them about a recent news event. If they are interested in sports or a particular sports team, questions related to the sport or team should be asked that any fan would know, such as the name of the team's manager or head coach, or the names and positions of top players.

Dementia and AD

Doctors use a number of methods to diagnose dementia and AD. Unfortunately, a definitive diagnosis of AD cannot be confirmed unless an **autopsy** is performed after death. Diagnosis before death is based upon observational findings of unexplained, slowly progressive dementia and brain-imaging studies that show a reduction in the size of the brain. Brain-imaging (neuroimaging) refers to the use of **positron emission tomography** (PET), **magnetic resonance imaging** (MRI), or computed topography (CT) scans. These are special types of pictures that allow the brain or other internal body structures to be visualized.

Tests that measure memory, language skills, math skills, and other abilities related to mental functioning are also used to help the physician accurately diagnose a patient's condition. For example, people with dementia or AD often show changes in executive functions (such as problem-solving), memory, and the ability to perform once-automatic tasks. Diagnosis is established after first excluding other possible causes for dementia or AD. It is important that any treatable conditions, such as depression, normal pressure **hydrocephalus**, or vitamin B_{12} deficiency, which cause similar symptoms are ruled out. Early, accurate diagnosis of dementia and AD is important for patients and their families because it allows early treatment of symptoms. For people with AD or other progressive dementias, early diagnosis may allow them to plan for the future while they can still help to make decisions. These patients also may benefit from drug treatment.

Treatment

The clinical effectiveness of treating mild memory impairment where no specific medical cause has been identified has yet to be fully tested. It is believed that these individuals might represent patients who are just beginning to develop AD and might benefit more from available treatments for AD than those patients with dementia. Besides drugs, other ways to improve memory in older adults is to learn a new skill, such as using the Internet; using memory tools such as appointment calendars and making to-do lists, and reminder notes; getting adequate sleep; exercising regularly; eating a healthy diet; and restricting alcohol consumption.

There is no cure for dementia and there are no treatments that reverse or halt disease progression for most of the dementias. Patients can benefit to some extent from treatment with available medications and other measures, such as cognitive training. Many people with dementia, particularly those in the early

WWW.BOOKBAZ.IR

stages, may benefit from practicing tasks designed to improve performance in specific aspects of cognitive functioning. For example, people can sometimes be taught to use memory aids, such as mnemonics, computerized recall devices, or note taking. Behavior modification—rewarding appropriate or positive behavior and ignoring inappropriate behavior—also may help control unacceptable or dangerous behaviors associated with dementia.

There is no cure for AD. However, medicines that treat the symptoms of AD are available and work best for patients in the early stage of the disease. Some medicines keep memory loss and other symptoms from getting worse for a time. Other medicines work to help people with AD sleep better or feel less worried and depressed. These medicines do not directly treat the disease, but they do help patients feel more comfortable in their surroundings.

As of 2014, there were five oral drugs approved by the U.S. Food and Drug Administration (FDA) to control the symptoms of AD and slow its progression. Four of these drugs, called cholinesterase inhibitors, slow the metabolic breakdown of acetylcholine, an important brain chemical involved in nerve cell communication. These drugs make more of this chemical available for communication between cells, which in turn slows the progression of cognitive impairment. Cholinesterase inhibitors can be effective for patients with mild to moderate symptoms of AD. These four drugs are tacrine (Cognex), donepezil (Aricept), rivastigmine (Exelon), and galantamine (Razadyne). In 2006, the FDA approved the use of donepezil to treat severe symptoms of AD and in 2007, approved rivastigmine in a patch form that delivers the drug through the skin. The fifth drug, memantine (Namenda), is approved to treat moderate to severe AD. Adverse side effects of all five drugs include nausea, **dizziness**, **headache**, and **fatigue**. Some of these drugs also are used to treat non-AD types of dementia.

Nutrition/Dietetic concerns

Several studies have found that high fat and high calorie **diets** may increase the risk of developing AD and other types of progressive dementia. Other risk factors for dementia and AD include alcohol, salt, and refined carbohydrates. It is recommended that patients with dementia avoid environmental toxins, such as tobacco smoke.

The incidence of AD in European and North American countries has been shown to be reduced with fish consumption. Researchers speculate that **Omega-3 fatty acids** in fish may delay the onset of AD. Anti-inflammatory agents, such as **antioxidants**, have shown some effectiveness in treating dementia. A diet that includes antioxidants such as vitamin C, **vitamin E**, selenium, green tea, and **ginkgo biloba** extract, may be beneficial. Ginkgo biloba, in addition to its antioxidant properties, increases blood and oxygen flow to the brain, thereby boosting brain function.

Therapy

For mild memory loss, therapy may include activities such as playing cards, board games, and word games like crossword puzzles and anagrams. Reading books, magazines, or newspapers regularly, and then discussing them with friends, relatives, or caregivers also aids memory retention.

There are no specific therapies associated with dementia or AD. A patient with these disorders is encouraged to **exercise** as much as their symptoms or physical limitations allow. Daily supervised walks are a good general exercise for people with severe memory impairment. Physicians recommend that people with dementia or AD try to live as normal a life as possible. This includes maintaining contact with and visiting friends and relatives, and maintaining their usual daily routines. Caregivers can assist with these recommendations.

Prognosis

Only about 15% of people with mild memory loss progress to dementia or AD. The other 85% continues to live a relatively normal life with memory loss causing only minimal interference in their daily lives. Patients with dementia or AD typically survive 8–10 years after diagnosis. Death is most frequently related to **malnutrition**, secondary infection (infection that is not the initial medical problem, such as **pneumonia**) or **heart disease**. Malnutrition is a state in which not enough calories are taken in to support the normal functions of the human body. Malnourished people are also more prone to infections. There is no evidence that links AD to heart disease, but the rate for both increases as people age.

Prevention

Restricting alcohol intake to one or two drinks a day or less, not **smoking**, eating a healthy diet, and exercising both mentally and physically on a regular basis can prevent or delay the onset of mild memory loss. Higher education achievement seems to reduce risk, but this may be related to people of higher education remaining more mentally active in retirement.

As of early 2015, there was no known way to prevent dementia or AD. A number of studies in laboratory mice indicate that a Mediterranean-style diet low in sugar and saturated animal fat, and high in fruits, vegetables, and whole-grains may reduce the risk of developing abnormal memory loss, including dementia. Several studies also suggest that a glass of red wine once a day may provide protection against memory loss.

Research has revealed a number of other factors that may prevent or delay the onset of memory loss some people. For example, studies have shown that people with diabetes who maintain tight control over glucose (sugar) levels in their blood tend to score better on tests of cognitive function than those with poorly controlled diabetes. Several studies also suggest that people who engage in intellectually stimulating activities, such as social interactions, chess, crossword puzzles, and playing a musical instrument significantly lower their risk of developing forms of dementia. Mental activities may stimulate the brain in a way that increases a person's cognitive reserve—the ability to cope with or compensate for the pathologic changes associated with dementia.

Care giver concerns

Caring for a person with severe memory loss at home is a difficult task and can become overwhelming. Each day brings new challenges as the caregiver copes with changing levels of ability and new patterns of behavior. Caregivers themselves often are at increased risk for depression and illness, especially if they do not receive adequate support from family, friends, and the community. A major struggle caregivers face is dealing with the difficult behaviors of the person they are caring for. Basic activities of daily living such as dressing, bathing, and eating often become difficult to manage for both the person with severe memory loss and the caregiver. Having a plan for getting through the day can help caregivers cope.

Each person with severe memory loss is unique and responds differently. Caregivers should remain calm and offer reassurance to the person in their care. Community organizations are often available to provide assistance and support groups for caregivers can provide a place to express their feelings and help anticipate future challenges. The person with severe memory loss must be monitored closely when they are unable to determine their own care. Caregivers should learn to recognize signs that the memory loss is getting progressively worse.

KEY TERMS

Amnesic—Relating to amnesia, the loss of memory.

Amyloid plaque—A waxy, translucent substance composed of complex protein fibers and polysaccharides that forms in body tissues in some degenerative diseases, such as Alzheimer's disease.

Antioxidant—A substance that inhibits the destructive effects of oxidation in the body.

Computed tomography (CT) scan—A diagnostic radiological scan in which cross-sectional images of the body are formed and shown on a computer screen.

Delusion—A persistent false belief held in the face of strong contradictory evidence.

Dementia—A usually progressive deterioration of intellectual functions, such as memory, that can occur while other brain functions such as those controlling movement and the senses are retained.

Genetic disease—A disease that is inherited from one or both parents.

Hydrocephalus—An increase of cerebrospinal fluid around the brain, resulting in an enlarged head.

Magnetic resonance imaging (MRI)—An imaging technique that uses electromagnetic radiation to obtain images of the body's soft tissues.

Parkinson's disease—A progressive nervous disorder marked by symptoms of trembling hands, lifeless face, monotone voice, and a slow shuffling walk.

Positron emission tomography (PET)—A method of medical imaging capable of displaying the metabolic activity of organs in the body that is useful in investigating brain disorders.

Tomography—A technique of using ultrasound, gamma rays, or x rays to produce a focused image of the structures across a specific depth within the body, while blurring details at other depths.

Ménière's disease

Definition

Ménière's disease is a condition characterized by recurrent vertigo (**dizziness**), **hearing loss**, and **tinnitus** (a roaring, buzzing or ringing sound in the ears).

Description

Ménière's disease was named for the French physician Prosper Ménière, who first described the illness in 1861. It is an abnormality within the inner ear. A fluid called endolymph moves in the membranous labyrinth or semicircular canals within the bony labyrinth inside the inner ear. When the head or body moves, the endolymph moves, causing nerve receptors in the membranous labyrinth to send signals to the brain about the body's motion. A change in the volume of the endolymph fluid, or swelling or rupture of the membranous labyrinth, is thought to result in Ménière's disease symptoms.

Causes and symptoms

Causes

The cause of Ménière's disease is unknown; however, scientists study several possible causes, including noise pollution, viral infections, or alterations in the patterns of blood flow in the structures of the inner ear. Since Ménière's disease sometimes runs in families, researchers are also looking into genetic factors as possible causes of the disorder.

One area of research that shows promise is the possible relationship between Ménière's disease and **migraine headache**. Dr. Ménière himself suggested

the possibility of a link, but early studies yielded conflicting results. A rigorous German study published in late 2002 reported that the lifetime prevalence of migraine was present in 56% of patients diagnosed with Ménière's disease as compared to 25% for controls. The researchers noted that further work is necessary to determine the exact nature of the relationship between the two disorders.

A study published in late 2002 reported that there is a significant increase in the number of CD4 cells in the blood of patients having an acute attack of Ménière's disease. CD4 cells are a subtype of T cells, which are produced in the thymus gland and regulate the immune system's response to infected or malignant cells. Further research is needed to clarify the role of these cells in Ménière's disease.

Another possible factor in the development of Ménière's disease is the loss of myelin from the cells surrounding the vestibular nerve fibers. Myelin is a whitish fatty material in the cell membrane of the Schwann cells that form a sheath around certain nerve cells. It acts like an electrical insulator. A team of researchers at the University of Virginia reported in 2002 that the vestibular nerve cells in patients with unilateral Ménière's disease are demyelinated; that is, they have lost their protective "insulation." The researchers are investigating the possibility that a viral disease or disorder of the immune system is responsible for the demyelination of the vestibular nerve cells.

Symptoms

The symptoms of Ménière's disease are associated with a change in fluid volume within the labyrinth of the inner ear. Symptoms include severe dizziness or vertigo, tinnitus, hearing loss, and the sensation of **pain** or pressure in the affected ear. Symptoms appear suddenly, last up to several hours, and can occur as often as daily to as infrequently as once a year. A typical attack includes vertigo, tinnitus, and hearing loss; however, some individuals with Ménière's disease may experience a single symptom, like an occasional bout of slight dizziness or periodic, intense ringing in the ear. Attacks of severe vertigo can force the sufferer to have to sit or lie down, and may be accompanied by **headache**, nausea, **vomiting**, or **diarrhea**. Hearing tends to recover between attacks, but becomes progressively worse over time.

Ménière's disease usually starts between the ages of 20 and 50 years; however, it is not uncommon for elderly people to develop the disease without a previous history of symptoms. Ménière's disease affects men and women in equal numbers. In most patients only one ear is affected but in about 15% both ears are involved.

Diagnosis

An estimated 3–5 million people in the United States have Ménière's disease, and almost 100,000 new cases are diagnosed each year. Diagnosis is based on medical history, **physical examination**, hearing and **balance tests**, and medical imaging with **magnetic resonance imaging** (MRI).

Several types of tests may be used to diagnose the disease and to evaluation the extent of hearing loss. In patients with Ménière's disease, audiometric tests (hearing tests) usually indicate a sensory type of hearing loss in the affected ear. Speech discrimination or the ability to distinguish between words that sound alike is often diminished. In about 50% of patients, the balance function is reduced in the affected ear. An electronystagnograph (ENG) may be used to evaluate balance. Since the eyes and ears work together through the nervous system to coordinate balance, measurement of eye movements can be used to test the balance system. For this test, the patient is seated in a darkened room and recording electrodes, similar to those used with a heart monitor, are placed near the eyes. Warm and cool water or air are gently introduced into the each ear canal and eye movements are recorded.

Another test that may be used is an electrocochleograph (EcoG), which can measure increased inner ear fluid pressure.

Treatment

There is no cure for Ménière's disease, but medication, surgery, and dietary and behavioral changes, can help control or improve the symptoms.

Medications

Symptoms of Ménière's disease may be treated with a variety of oral medicine or through injections. **Antihistamines**, like diphenhydramine, meclizine, and cyclizine can be prescribed to sedate the vestibular system. A barbiturate medication like pentobarbital may be used to completely sedate the patient and relieve the vertigo. Anticholinergic drugs, like atropine or scopolamine, can help minimize **nausea and vomiting**. Diazepam has been found to be particularly effective for relief of vertigo and nausea in Ménière's disease. There have been some reports of successful control of vertigo after **antibiotics** (gentamicin or streptomycin) or a steroid medication (dexamethasone) are injected directly into the inner ear. Some researchers have found that gentamicin is effective in relieving tinnitus as well as vertigo.

WWW.BOOKBAZ.IR

A newer medication that appears to be effective in treating the vertigo associated with Ménière's disease is flunarizine, which is sold under the trade name Sibelium. Flunarizine is a **calcium** channel blocker and anticonvulsant that is presently used to treat Parkinson's disease, migraine headache, and other circulatory disorders that affect the brain.

Surgical procedures

Surgical procedures may be recommended if the vertigo attacks are frequent, severe, or disabling and cannot be controlled by other treatments. The most common surgical treatment is insertion of a small tube or shunt to drain some of the fluid from the canal. This treatment usually preserves hearing and controls vertigo in about one-half to two-thirds of cases, but it is not a permanent cure in all patients.

The vestibular nerve leads from the inner ear to the brain and is responsible for conducting nerve impulses related to balance. A vestibular neurectomy is a procedure where this nerve is cut so the distorted impulses causing dizziness no longer reach the brain. This procedure permanently cures the majority of patients and hearing is preserved in most cases. There is a slight risk that hearing or facial muscle control will be affected.

A labyrinthectomy is a surgical procedure in which the balance and hearing mechanism in the inner ear are destroyed on one side. This procedure is considered when the patient has poor hearing in the affected ear. Labyrinthectomy results in the highest rates of control of vertigo attacks, however, it also causes complete deafness in the affected ear.

Alternatives

Changes in diet and behavior are sometimes recommended. Eliminating **caffeine**, alcohol, and salt may relieve the frequency and intensity of attacks in some people with Ménière's disease. Reducing **stress** levels and eliminating tobacco use may also help.

Acupuncture is an alternative treatment that has been shown to help patients with Ménière's disease. The World Health Organization (WHO) lists Ménière's disease as one of 104 conditions that can be treated effectively with acupuncture.

Prognosis

Ménière's disease is a complex and unpredictable condition for which there is no cure. The vertigo associated with the disease can generally be managed or eliminated with medications and surgery. Hearing tends to become worse over time, and some of the surgical procedures recommended, in fact, cause deafness.

KEY TERMS

Myelin—A whitish fatty substance that acts like an electrical insulator around certain nerves in the peripheral nervous system. It is thought that the loss of the myelin surrounding the vestibular nerves may influence the development of Ménière's disease.

T cell—A type of white blood cell produced in the thymus gland that regulates the immune system's response to diseased or malignant cells. It is possible that a subcategory of T cells known as CD4 cells plays a role in Ménière's disease.

Tinnitus—A roaring, buzzing or ringing sound in the ears.

Transcutaneous electrical nerve stimulation (TENS)—A treatment in which a mild electrical current is passed through electrodes on the skin to stimulate nerves and block pain signals.

Vertigo—The medical term for dizziness or a spinning sensation.

Prevention

Since the cause of Ménière's disease is unknown, there are no current strategies for its prevention. Research continues on the environmental and biological factors that may cause Ménière's disease or induce an attack, as well as on the physiological components of the fluid and labyrinth system involved in hearing and balance. Preventive strategies and more effective treatment should become evident once these mechanisms are better understood.

Meningitis

Definition

Meningitis is a potentially fatal inflammation of the meninges, the membranes that encase the brain and spinal cord. Meningitis is most commonly caused by viruses, but also may be caused by a bacterial, or less commonly, a fungal infection. Non infective causes of meningitis include certain drug **allergies**, some cancers, and **systemic lupus erythematosus** (SLE). Inflammation causes swelling of the brain. As the brain swells, fragile brain tissues are pressed against the skull. Brain cells in these areas can become damaged and eventually die.

Demographics

According to the Centers for Disease Control and Prevention (CDC), there are about 4,100 cases of bacterial meningitis in the United States each year, and about 500 people die of the disease annually. The introduction of Hib vaccine against *Haemophilus influenzae* in 1990 has changed the demographics of bacterial meningitis in North America, shifting the median age of this type of meningitis from less than 2 years of age to 39 years. In addition, in the 2000s, there was an increase in cases among adults over age 60.

People of any race can get meningitis; however, African Americans are more likely to get meningitis than either Caucasian or Hispanic Americans. Infant males in the United States are three times more likely to develop meningitis than infant females; the rates are similar for both genders in adults.

The rates of meningitis in developing countries are thought to be at least 10 times as high as those in the United States and Canada. The lack of vaccines in these countries is the major factor in the difference. Periodic epidemics occur in sub-Saharan Africa and parts of India.

Description

Doctors sometimes divide cases of meningitis into three categories according to the speed of symptom development. Acute meningitis develops in less than 24 hours and is caused by one of several species of bacteria; it is considered a medical emergency. Subacute meningitis takes between 1 and 7 days for symptoms to appear; it may be caused by bacteria or viruses. Chronic meningitis develops over a period of more than a week and may result from an infection or a noninfectious cause.

Structure of the brain

In order to understand why meningitis can be so dangerous, it is important to have a basic understanding of the anatomy of the brain. The meninges are three separate membranes, layered together, which encase the brain and spinal cord:

- The dura mater is the toughest, outermost layer, and is closely attached to the inside of the skull.

WWW.BOOKBAZ.IR

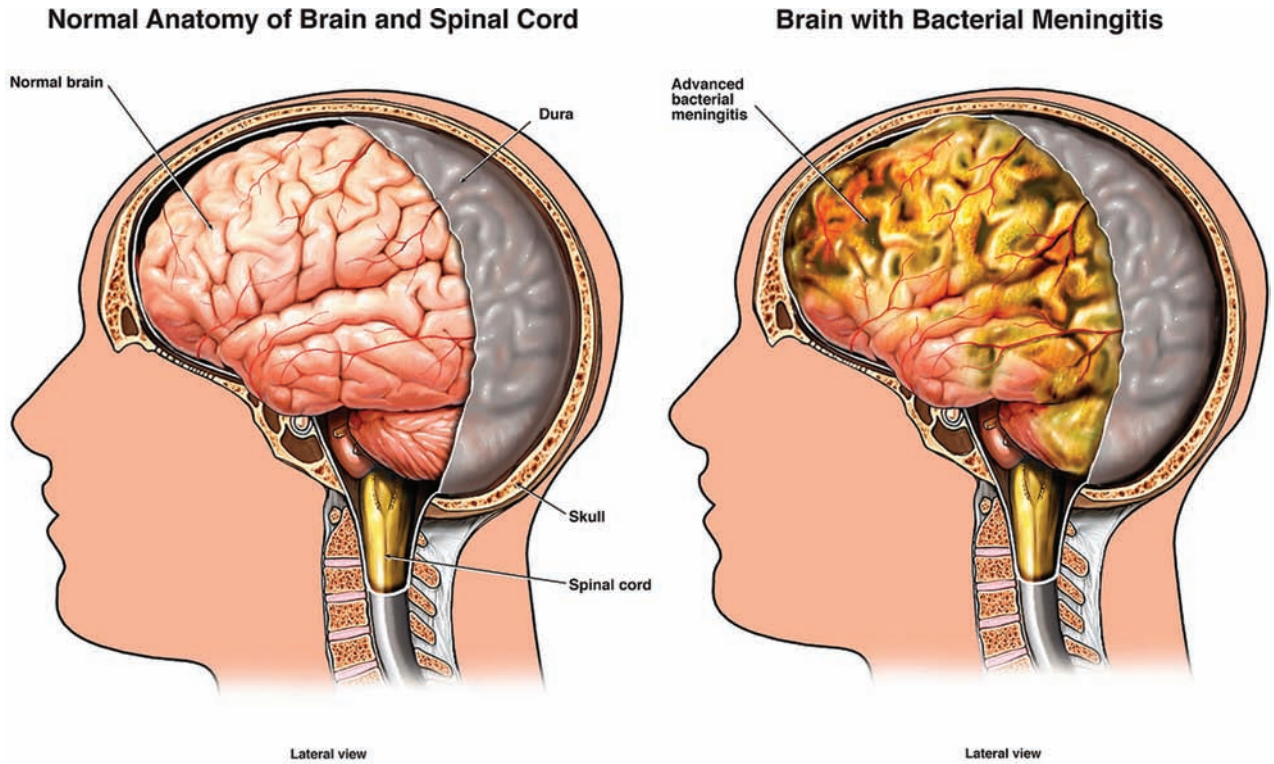

Illustration of bacterial meningitis in an adult. *(© PHOTOTAKE Inc./Alamy.)*

- The middle layer, the arachnoid mater, is important because of its involvement in the normal flow of the cerebrospinal fluid (CSF), a lubricating and nutritive fluid that bathes both the brain and the spinal cord.
- The innermost layer, the pia mater, helps direct blood vessels into the brain.
- The space between the arachnoid mater and the pia mater contains CSF, which helps insulate the brain from trauma. Many blood vessels, as well as peripheral and cranial nerves, pass through this space.

CSF, produced in specialized chambers deep inside the brain, flows over the surface of the brain and spinal cord. This fluid serves to cushion these relatively delicate structures, as well as supplying important nutrients for brain cells. CSF is reabsorbed by blood vessels located within the meninges. A careful balance between CSF production and reabsorption is important to avoid the accumulation of too much CSF.

Because the brain is enclosed in the hard, bony case of the skull, any disease that produces swelling will be damaging to the brain. The skull cannot expand at all, so when the swollen brain tissue pushes up against the skull's hard bone, the brain tissue becomes damaged and the blood supply is compromised, and this tissue may ultimately die. Furthermore, swelling on the right side of the brain will not only cause pressure and damage to that side of the brain, but by taking up precious space within the tight confines of the skull, the left side of the brain will also be pushed up against the hard surface of the skull, causing damage to the left side of the brain, as well.

Types of meningitis

Viral meningitis, which is also called aseptic meningitis, is the most common type of meningitis. It is a less severe infection than bacterial meningitis, is rarely fatal, and may not require any specific treatment. Viral meningitis is caused by one or more enteroviruses, which are viruses that normally live in the digestive tract. Viral meningitis usually develops in the late summer and early fall, and is most likely to affect children and adults under age 30. Most viral infections occur in children under the age of 5. Enteroviruses are present in saliva, throat mucus, and feces; they can be transmitted through direct contact with an infected person or an infected object or surface. Viral meningitis can also be caused by the viruses that cause **chickenpox**, **mumps**, HIV infection, **West Nile virus** infection, and **genital herpes**.

HATTIE ALEXANDER (1901–1968)

Dr. Hattie E. Alexander. *((c) BettmannCORBIS)*

Hattie Alexander, a dedicated pediatrician, medical educator, and researcher in microbiology, won international recognition for deriving a serum to combat influenzal meningitis, a common disease that previously had been nearly always fatal to infants and young children. Alexander subsequently investigated microbiological genetics and the processes whereby bacteria, through genetic mutation, acquire resistance to antibiotics. In 1964, as president of the American Pediatric Society, she was among the first women to head a national medical association.

As an intern at the Harriet Lane Home of Johns Hopkins Hospital from 1930 to 1931, Alexander became interested in influenzal meningitis. The source of the disease was *Hemophilus influenzae*, a bacteria that causes inflammation of the meninges, the membranes surrounding the brain and spinal cord. In 1931, Alexander began a second internship at the Babies Hospital of the Columbia-Presbyterian Medical Center in New York City. There, she witnessed first-hand the futility of medical efforts to save babies who had contracted influenzal meningitis.

Alexander's early research focused on deriving a serum (the liquid component of blood, in which antibodies are contained) that would be effective against influenzal meningitis. Serums derived from animals that have been exposed to a specific disease-producing bacterium often contain antibodies against the disease and can be developed for use in immunizing humans against it. Alexander knew that the Rockefeller Institute in New York City, however, had been able to prepare a rabbit serum for the treatment of pneumonia, another bacterial disease. Alexander therefore experimented with rabbit serums and by 1939 was able to announce the development of a rabbit serum effective in curing infants of influenzal meningitis.

In the early 1940s, Alexander experimented with the use of drugs in combination with rabbit serum in the treatment of influenzal meningitis. Within the next two years, she saw infant deaths due to the disease drop by eighty percent.

Bacterial meningitis is a medical emergency and has a high mortality rate if untreated. The origin of a bacterial infection leading to meningitis varies according to an individual's age, habits, geographical location, and health status. In newborns, the most common agents of meningitis are those contracted from the mother during labor and delivery, including the bacteria Group B streptococci, *Escherichia coli*, and *Listeria monocytogenes*. Older children are more frequently infected by *Haemophilus influenzae*, *Neisseria meningitidis*, and *Streptococcus pneumoniae* bacteria, while adults are infected by *S. pneumoniae* and *N. meningitidis*. Persons who have had pneumococcal meningitis may be left with lifelong damage to their nervous system that includes deafness and brain damage. *N. meningitidis* is highly contagious and can cause epidemics. Epidemics of meningitis most often occur under crowded conditions, such as day care centers, college residence halls, or military barracks. Meningococcal meningitis has a mortality rate of 10–15 %.

Meningitis caused by fungi is rare in the general population but is a fairly common opportunistic infection in patients with HIV infection.

Risk factors

Risk factors for meningitis include:

- age. Since the introduction of childhood vaccines, bacterial meningitis is now more common in young adults.
- group living situations. These may include military bases, college dormitories, and child care centers.
- having a weakened immune system. People with AIDS or diabetes are at increased risk of meningitis.

WWW.BOOKBAZ.IR

- working with animals. Farmers and others who work with animals have an increased risk of *Listeria* infections.
- pregnancy.
- spleen removal. People who have had their spleen (a part of the immune system) removed have weaker immune systems.
- gender. Among newborns, boys are 3 times more likely than girls to get meningitis.
- lifestyle. Unsafe sexual practices and having a large number of sexual partners increases the risk of viral meningitis.

Causes and symptoms

Meningitis occurs when disease organisms that have entered the body and multiplied in the nose, mouth, and throat get into the bloodstream and are carried to the brain and the meninges. In a few cases meningitis can develop when the bacteria gain entrance to the body through a surgical incision or an injury to the head or neck. A few cases of meningitis result from inflammatory diseases like lupus or certain cancers.

Organisms causing meningitis

About 90% of cases of viral meningitis are caused by viruses from the enterovirus family. Viruses from this family also cause viral **gastritis** (stomach flu). However, viruses that cause mumps, **measles**, and **polio** can also cause viral meningitis. Although these diseases are uncommon in developed countries, they are still prevalent in the developing world and may be of concern to travelers.

Bacterial meningitis is caused primarily by four types of bacteria.

- *Streptococcus pneumoniae*. Also called pneumococcal meningitis, this bacterium also causes pneumonia, ear, and sinus infections. It is a leading cause of bacterial meningitis in young children.
- *Neisseria meningitidis*. Also called meningococcal meningitis, this bacterium is highly contagious and is often responsible for outbreaks of meningitis among young adults.
- *Haemophilus influenzae*. Routine childhood vaccinations against Haemophilus bacteria have been available since the 1990s and in the developed world have substantially reduced this cause of meningitis.
- *Listeria monocytogenes*. Pregnant women and older adults are at higher risk than other groups for contracting listeria meningitis. Listeria can cross the placenta and kill a developing fetus.

Less common causes of meningitis include fungi, parasites, and noninfectious causes (such as meningeal inflammation and irritation caused by systemic disorders like lupus). Fungal meningitis tends to strike individuals who have immune disorders, with higher rates in people who have diabetes, cancer, or HIV-AIDS. Parasitic forms of meningitis occur at significantly higher rates in developing countries.

Methods of disease transmission

Bacterial meningitis can be passed from person to person through coughing, sneezing, or kissing, but the disease does not spread as easily as the **common cold**. Once in the body, the bacteria are carried to the brain through the blood. However, in some cases, a person may have another type of infection (for instance, infection of the lungs, throat, or tissues of the heart) caused by an organism that can also cause meningitis. If this initial infection is not properly treated, the organism will continue to multiply, find its way into the blood stream, and be delivered in sufficient quantities to invade past the blood-brain barrier. Direct spread occurs when an organism spreads to the meninges from infected tissue next to or very near the meninges. This can occur, for example, with a severe and poorly treated ear or sinus infection. Insect and pet bites can also deliver disease organisms directly into the bloodstream.

Patients who experience skull **fractures** have abnormal openings to the sinuses, nasal passages, and middle ears. Organisms that usually live in the human respiratory system without causing disease can pass through openings caused by such fractures, reach the meninges, and cause infection. Similarly, patients who undergo surgical procedures or who have had foreign bodies surgically placed within their skulls (such as tubes to drain abnormal amounts of accumulated CSF) have an increased risk of meningitis.

Disease organisms can also reach the meninges via an uncommon method called intraneural spread. Intraneural spread involves an organism invading the body at a considerable distance away from the head, spreading along a nerve, and using that nerve as a pathway into the skull, where the organism can multiply and cause meningitis. Herpes simplex virus is known to use this type of spread, as is the **rabies** virus.

Symptoms

The most important symptoms used to diagnose meningitis are a high **fever**, stiff neck, and severe

headache, which may come on in less than a day after infection. Other symptoms in adults may include:

- nausea and vomiting
- extreme sensitivity to light (photophobia)
- confusion and difficulty concentrating
- seizures
- loss of appetite
- drowsiness or difficulty waking up
- skin rash (more common with meningococcal meningitis)

Infants and small children may have somewhat different symptoms:

- bulging of the soft spot (fontanelle) at the top of an infant's skull
- constant crying
- poor feeding
- unusual sleepiness
- stiffness in the baby's body as well as neck

It is important to note that very young infants may not show the classic signs of meningitis. Early in infancy, a baby's immune system is not yet developed enough to mount a fever in response to infection, so fever may be absent. In some infants with meningitis, seizures are the only identifiable symptom. Similarly, debilitated elderly people may not have fever or other clearly identifiable symptoms of meningitis.

Diagnosis

Diagnosis of the cause of meningitis is essential to proper treatment, as the **antibiotics** used to treat bacterial meningitis are not useful in treating viral meningitis. A patient who has acute bacterial meningitis will usually have treatment started as soon as the doctor obtains a sample of cerebrospinal fluid for testing. The CSF is obtained by performing a **lumbar puncture**, also known as a spinal tap. This is a procedure in which a needle is inserted into an area in the lower back where the doctor can easily obtain a sample of cerebrospinal fluid.

Examination

An examination of a patient with suspected meningitis will include a recent history of the patient's activities to indicate possible exposure to disease agents, such as recent travel, contact with infected persons, or contact with animals or insects. The season of the year may be an important diagnostic clue; **enterovirus infections** are more common in North America in late summer and early fall, while insect-borne infections are more common in late spring and summer. The doctor will also perform a neurological examination, which includes testing of the patient's hearing and speech, vision, coordination and balance, reflexes, mental status, and recent changes in mood or behavior. In addition, certain manipulations of the patient's head (lowering the head, chin toward chest, for example) are difficult to perform and painful for a person with meningitis.

KEY TERMS

Arachnoid mater—The middle layer of the meninges.

Aseptic meningitis—A term that is sometimes used for meningitis that is not caused by bacteria.

Blood-brain barrier—An arrangement of cells within the blood vessels of the brain that prevents the passage of toxic substances, including infectious agents, to move from the blood into the brain. It also makes it difficult for certain medications to pass into brain tissue.

Cerebrospinal fluid (CSF)—Fluid made in chambers within the brain which then flows over the surface of the brain and spinal cord. CSF provides nutrition to cells of the nervous system, as well as providing a cushion for the structures of the central nervous system.

Dura mater—The outermost layer of the meninges.

Enteroviruses—A family of viruses that normally live in the digestive tract.

Hydrocephalus—Abnormal accumulation of cerebrospinal fluid within the cavities inside the brain.

Lumbar puncture (LP)—A medical test in which a very narrow needle is inserted into a specific space between the vertebrae of the lower back in order to obtain a sample of CSF for examination. It is also known as a spinal tap.

Meninges (singular, meninx)—The membranes that cover the brain and spinal cord.

Opportunistic infection—An infection caused by an organism that does not cause disease in a person with a healthy immune system.

Photophobia—Abnormal sensitivity to light.

Pia mater—The innermost layer of the meninges.

Systemic lupus erythematosus (SLE)—A chronic, inflammatory, autoimmune disorder in which the individual's immune system attacks, injures, and destroys the body's own organs and tissues. It may affect many organ systems including the skin, joints, lungs, heart, and kidneys.

WWW.BOOKBAZ.IR

A patient with subacute meningitis may be given an examination to check for an ear, throat, or sinus infection. In addition to moving the patient's head, the doctor may also perform two other maneuvers to see whether the patient's meninges are inflamed. In one test, the doctor raises the patient's leg at the hip to a right angle from the examining table and tries to straighten the lower leg. If the leg cannot be straightened or if the patient experiences neck **pain**, he or she most likely has meningitis. The other maneuver involves bending the patient's neck forward as they lie on the table. If the knees and hips flex upward, the patient probably has meningitis.

Tests

If a sample of CSF is taken, it is sent to a laboratory for analysis. The CSF is then examined under a microscope to look for bacteria or fungi. Normal CSF contains set percentages of glucose and protein. These percentages will vary with bacterial, viral, or other causes of meningitis. For example, bacterial meningitis causes a smaller than normal percentage of glucose to be present in CSF, as the bacteria are essentially "eating" the host's glucose and using it for their own **nutrition** and energy production. Normal CSF should contain no infection-fighting cells (white blood cells), so the presence of white blood cells in CSF is another indication of meningitis. Some of the withdrawn CSF is also put into special lab dishes to allow growth of the suspected infecting organism, which can then be identified more easily.

Identification of the specific bacterium can take as long as a week; meanwhile, the doctor can begin to treat the patient with a broad-spectrum antibiotic until the test results come back. In some cases the doctor will swab the patient's throat to obtain a sample of mucus and saliva for culture. The sample can be sent to a local or state laboratory or to the CDC for analysis. Throat cultures usually take between 2 and 3 days to yield results.

In March 2007 the Food and Drug Administration (FDA) approved a rapid CSF test that identifies virus particles in CSF called the Xpert EV test. Using a sample of CSF, this test can accurately identify about 90% of viral meningitis cases in less than three hours. Since bacterial meningitis is often fatal, if no virus is found in the CSF, the disease is treated as if it is caused by bacteria until proven otherwise. This test allows doctors to distinguish fairly quickly between viral and bacterial meningitis and avoid giving unnecessary antibiotics to patients with viral meningitis.

The doctor may also order such imaging tests as a computed tomography (CT) scan or **magnetic resonance imaging** (MRI). A CT scan may detect signs of inflammation of the meninges. Imaging tests can also be used to rule out head **trauma**, **stroke**, tumors, and **blood clots** in the brain.

Treatment

Meningitis is a medical emergency. Individuals with the symptoms of meningitis must get to a hospital as quickly as possible, particularly if the symptoms have developed in less than one day. People who are acutely ill and are taken to a hospital are usually treated within 30 minutes of their arrival, as emergency room doctors assume that the patient has bacterial meningitis and do not want to delay treatment until the specific organism is identified. A sample of cerebrospinal fluid is taken by a spinal tap for analysis; then the patient is given intravenous penicillin or another broad-spectrum antibiotic, intravenous fluids, and pure oxygen to assist breathing. The patient may also need to be treated for seizures or to have fluid drained from the sinuses or from the space between the meninges and the brain. After the specific bacterium has been identified, the doctor can adjust the type and dosage of the antibiotics given to the patient. People with bacterial meningitis may need additional treatment for **shock**, seizures, **dehydration**, and brain swelling. Serious cases of bacterial meningitis may require treatment in an intensive care unit (ICU) and **life support**.

Viral meningitis cannot be treated with antibiotics. Patients are usually advised to stay home and rest in bed for a few weeks. They can take over-the-counter pain relievers for muscle aches and pains and to bring down fever. If the viral meningitis is caused by the herpes virus, the doctor may also prescribe acyclovir or gancyclovir, **antiviral drugs** used to treat herpes.

Drugs

Bacterial meningitis is usually treated with a combination of intravenous antibiotics. The specific combination depends on the patient's age and immune status; however, most antibiotic combinations consist of ampicillin (Marcillin, Omnipen) plus cefotaxime (Claforan) or ceftriaxone (Rocephin) plus vancomycin (Vancocin). Treatment is given for 7–10 days for less severe infections to 14–21 days for severe infections. In some cases the patient may also be given **steroids**, most commonly dexamethasone, to reduce inflammation caused by the bacteria.

Alternatives

Because meningitis is a potentially deadly condition, traditional medical doctors should be contacted immediately for diagnosis and treatment. Alternative treatments should be used only to support the recovery process following appropriate antibiotic treatments, or used concurrently with antibiotic treatments.

Alternative therapies, such as homeopathy, **traditional Chinese medicine**, and Western herbal medicine may help patients regain their health and build up their immune systems. The recovering individual, under the direction of a professional alternative therapist, may opt to include mushrooms into his or her diet to stimulate immune function. The patient should contact an experienced herbalist or homeopathic practitioner for specific remedies.

Prognosis

The patient's prognosis depends on the type of meningitis that they have as well as their overall health. Patients who experience only headache, fever, and stiff neck may recover in 2–4 weeks. Patients with bacterial meningitis typically show some relief within 48 to 72 hours following initial treatment; however, they are more likely to experience complications caused by the disease. Acute bacterial meningitis has a mortality rate of 10–15 percent even with treatment. The reported mortality rates for each specific organism are 19–26% for *S. pneumoniae* meningitis, 3–6% for *H. influenzae* meningitis, 3–13% for *N. meningitidis* meningitis, and 15–29% for *L. monocytogenes* meningitis. Pneumococcal meningitis may have a mortality rate as high as 21 percent. Of the patients who survive bacterial meningitis, between 10 and 20 percent will suffer such complications as blindness, **hydrocephalus**, **hearing loss**, **learning disorders**, or even **paralysis**. Scarring of the meninges may result in obstruction of the normal flow of CSF, causing abnormal accumulation of CSF. This may be a chronic problem for some people, requiring the installation of shunt tubes to drain the accumulation on a regular basis.

Viral meningitis is usually a much milder disease than bacterial meningitis. Patients receiving treatment for viral meningitis and encephalitis usually see some relief in 24–48 hours. Some patients may need to be hospitalized for supportive care for a week or so, but most can recover at home within two to four weeks. Complications are rare with viral meningitis; the mortality rate is less than 1%.

Prevention

As of 2010, several vaccines could be used to prevent meningitis. The rates of *Haemophilus influenzae* meningitis among young children dropped dramatically after the Hib vaccine was added to childhood immunization schedules in the 1990s. Other vaccines have been developed to protect adults as well as children from pneumococcal and meningococcal meningitis. There is one type of pneumococcal vaccine known as PCV7, recommended for children between 2 and 5 years of age who are at high risk of infection.

A different vaccine known as PPV is recommended for adults at risk of pneumococcal meningitis: those over 65, those with weakened immune systems, those with diabetes or **heart disease**, and those whose spleen was removed. The vaccine that protects against the meningococcus is known as Menactra or MCV4. It is recommended for all children at 11–12, with a booster given at age 16. Many colleges require that students have been fully vaccinated against this disease. MCV4 can also be used to protect people exposed to meningitis during an outbreak or who must travel to countries with high rates of meningococcal meningitis. Adults over 55 should be immunized with a similar vaccine called MPSV4, a meningococcal polysaccharide vaccine known as Menomune.

Other preventive measures that people can take include:

- Keeping the immune system strong by getting enough sleep, exercising regularly, and eating a healthy diet
- Washing the hands regularly, particularly when living in a dormitory or similar shared housing situation
- Avoiding sharing glasses, drinking cups, food utensils, and similar items with others who may be infected or exposed to infection
- Covering the mouth or nose before sneezing or coughing
- Taking any antibiotics that may be prescribed during a meningitis outbreak in one's school or workplace
- Asking the doctor about vaccination against meningitis before traveling abroad

Meningococcemia

Definition

Meningococcemia is the presence of meningococcus in the bloodstream. Meningococcus, a bacteria formally called *Neisseria meningitidis*, can be one of the most dramatic and rapidly fatal of all infectious diseases.

Causes and symptoms

Meningococcemia, a relatively uncommon infection, occurs most commonly in children and young adults. In susceptible people, it may cause a very severe illness that can produce death within hours. The bacteria, which can spread from person to person, usually first causes a colonization in the upper airway, but without symptoms. From there, it can penetrate into the bloodstream to the central nervous system and cause **meningitis** or develop into a full-blown bloodstream infection (meningococcemia). Fortunately in most colonized people, this does not happen and the result of this colonization is long-lasting immunity against the particular strain.

After colonization is established, symptoms can develop within one day to one to two weeks. After a short period of time (one hour up to one to two days) when the patient complains of **fever** and muscle aches, more severe symptoms can develop. Unfortunately during this early stage, a doctor cannot tell this illness from any other illness, such as a viral infection like **influenza**. Unless the case is occurring in a person known to have been exposed to or in the midst of an

A close-up image of a person's hand with meningococcemia. This disease is caused by the presence of meningococcus (*Neisseria meningitidis*) in the bloodstream. The organism can cause multiple illnesses and can damage small *(Custom Medical Stock Photo, Inc.)*

epidemic of meningococcal disease, there may be no specific symptoms or signs found that help the doctor diagnose the problem. Rarely, a low-grade bloodstream infection called chronic meningococcemia can occur.

After this initial period, the patient will often complain of continued fever, shaking chills, overwhelming weakness, and even a feeling of impending doom. The organism is multiplying in the bloodstream, unchecked by the immune system. The severity of the illness and its dire complications are caused by the damage the organism does to the small blood vessel walls. This damage is called a **vasculitis**, an inflammation of a blood vessel. Damage to the small vessels causes them to become leaky. The first signs of the infection's severity are small bleeding spots seen on the skin (petechiae). A doctor should always suspect meningococcemia when he/she finds an acutely ill patient with fever, chills, and petechiae.

Quickly (within hours), the blood vessel damage increases and large bleeding areas on the skin (purpura) are seen. The same changes are taking place in the affected person's internal organs. The blood pressure is often low and there may be signs of bleeding from other organs (like coughing up blood, nose bleeds, blood in the urine). The organism not only damages the blood vessels by causing them to leak, but also causes clotting inside the vessels. If this clotting occurs in the larger arteries, it results in major tissue damage. Essentially, large areas of skin, muscle, and internal organs die from lack of blood and oxygen. Even if the disease is quickly diagnosed and treated, the patient has a high risk of dying.

Diagnosis

The diagnosis of meningococcemia can be made by the growth of the organism from blood cultures. Treatment should begin when the diagnosis is suspected and should not be delayed waiting for positive cultures. Obtaining fluid from a petechial spot and staining it in the laboratory can assist in quickly seeing the organism.

Treatment

Immediate treatment of a suspected case of meningococcemia begins with **antibiotics** that work against the organism. Possible choices include penicillin G, ceftriaxone (Rocephin), cefotaxime (Claforan), or trimethoprim/sulfamethoxazole (Bactrim, Septra). If the patient is diagnosed in a doctor's office, antibiotics should be given immediately if possible, even before transfer to the hospital and even if cultures cannot be obtained before treatment. It is most likely that the speed of initial treatment will affect the ultimate outcome.

KEY TERMS

Blood culture—A procedure where blood is collected from a vein and is placed in a small bottle that contains a special liquid; the liquid will make any organisms that are present in the blood sample grow. These organisms can then be grown and identified in the laboratory so that the proper antibiotic can be given to the patient.

Colonization—The presence of bacteria on a body surface (like on the skin, mouth, intestines or airway) without causing disease in the person.

Complement—One of several proteins in the blood that acts with other proteins to assist in killing bacteria.

Meningitis—Inflammation of the membranes of the brain or spinal cord.

Prognosis

As many as 15-20% of patients with meningococcemia will die as a result of the acute infection. A significant percentage of the survivors will have tissue damage that requires surgical treatment. This treatment may consist of skin grafts, or even partial or full amputations of an arm or leg. Certain people with immune system defects (particularly those with defects in the complement system) may have recurrent episodes of meningococcemia. These patients, however, seem to have a less serious outcome.

Prevention

Although a vaccine is available for meningococcus, it is still difficult at this time to produce a vaccine for the type B organism, the most common one in the United States. Because of this and the short time that the vaccine seems to offer protection, the product has not been routinely used in the United States. It can be used for travelers going to areas where meningococcal disease is more common or is epidemic. The vaccine has been suggested for use in incoming college freshman, particularly those living in dormitories. These students appear to have a somewhat higher risk of meningococcal infections.

It is, however, recommended that all people take certain antibiotics if they have had contact (like at

WWW.BOOKBAZ.IR

home or in a daycare) with a person who has meningococcal infection. The most common antibiotics given are rifampin (Rifadin) or ciprofloxacin (Cipro). These medicines are usually taken by mouth twice a day for two days. This treatment will decrease the risk of infection in these people who have been exposed. However, the overall risk to people who have been exposed, even without antibiotic use, is probably no more than 1-2%.

Menopause

Definition

Menopause represents the irreversible end of ovulation and menstruation. Technically menopause refers to the final menstrual period after which a woman can no longer conceive children. Nevertheless, menopause is not an abrupt event, but a gradual process that involves many physical and hormonal changes before fertility ceases. Menopause is not a disease that needs to be treated, but a natural result of **aging**. However, the changes that occur during the time surrounding menopause can cause symptoms of widely varying severity that women may wish to treat. Women have many options for managing these symptoms.

Description

Perimenopause is the time surrounding menopause. It can last for several years, and many women have irregular periods and other changes during this time. Although it is not easy to pinpoint when menopause begins, many doctors agree that it is complete when a woman has not had a menstrual period for a full year.

There is no method to determine when the ovaries will begin to scale back, but a woman can get a general idea of when she will experience menopause based on her family history, body type, and lifestyle. A woman is likely to enter menopause at about the same age as her mother and sisters. Women who are smokers are more likely to begin menopause earlier than nonsmokers. Women who began menstruating early will not necessarily stop having periods early. Eight out of every 100 women stop menstruating before age 40. At the other end of the spectrum, five out of every 100 continue to have periods until they are almost 60. The average age of menopause is 51.

Causes and symptoms

Once a woman enters **puberty**, her body releases one of the more than 400,000 eggs (ova) that are stored in her ovaries, about every 28 days in response to the interaction of several hormones. Blood supply to the womb (uterus) increases, and the lining of the uterus thickens in anticipation of receiving a fertilized egg. If the egg is not fertilized, the level of progesterone, the hormone mainly responsible for this uterine thickening, drops, and the uterine lining is sloughed off along with some blood. This menstrual flow is visible evidence ovulation has occurred.

By the time a woman reaches her late 30s or 40s, her ovaries begin to produce less of the female hormones estrogen and progesterone and to release eggs less regularly. As the levels of hormones fluctuate, the menstrual cycle begins to change. Some women may have longer periods with heavy flow followed by shorter cycles and very little bleeding. Others will begin to miss periods entirely. These irregular menstrual cycles make it more difficult for a woman to become pregnant. The gradual decline of estrogen also causes a wide variety of changes in tissues that respond to estrogen including the vagina, vulva, uterus, bladder, urethra, breasts, bones, heart, blood vessels, brain, skin, hair, and mucous membranes. Less immediately, the long-term lack of estrogen can make a woman more vulnerable to **osteoporosis**.

The most common symptom of perimenopause include:

- changes in the menstrual cycle
- hot flashes
- night sweats
- insomnia
- mood swings and increased irritability
- memory or concentration problems
- vaginal dryness
- heavy bleeding
- fatigue
- depression
- changes in the thickness and texture of hair
- headaches

- heart palpitations
- sexual disinterest
- urinary changes
- weight gain

Diagnosis

The clearest indication of menopause is the absence of a period for one full year. If it has been at least three months since a woman's last period, a follicle-stimulating hormone (FSH) test might be helpful in determining whether menopause has occurred. FSH levels rise steadily as a woman ages. The FSH test alone cannot be used as proof that a woman has entered early menopause. A better measure of menopause is to determine the levels of FSH, estrogen, progesterone, testosterone, and related hormones at mid-cycle. These tests are not routinely performed as most women can recognize the symptoms of perimenopause and menopause. They can, however, be helpful diagnostic tests in younger women who are showing symptoms of perimenopause.

Treatment

Decisions about if and how to treat symptoms associated with perimenopause should be made by a woman and her healthcare provider after taking into consideration her medical history and current research findings. Some women report success in using natural remedies to treat the unpleasant symptoms of menopause, although alternative therapies only received significant attention in the United States in the first decade of the twenty-first century. Debate continues until scientific studies can prove these treatments' effectiveness on menopausal symptoms.

For women nearing menopause, alternative medical practitioners and traditional healthcare professionals generally recommend a diet high in fresh fruits, fresh vegetables, whole grains, nuts, seeds, and fresh vegetable juices and low in sugary treats and fats, especially animal fats. Calorie and portion control becomes more important as metabolism slows. Because a decrease in estrogen accelerates bone loss, women should make sure they get enough **calcium**. Most often a calcium supplement is recommended in addition to dairy products that provide calcium. Women generally need less iron after menopause because they no longer bleed monthly.

Herbs

Herbs have been used to relieve menopausal symptoms for centuries. In reasonable quantities, many herbs are relatively safe. Often adverse reactions to herbs come not from the herbs themselves, but from contaminants. Because the United States Food and Drug Administration (FDA) does not regulate herbal products as strictly as pharmaceutical medicines, contamination, mislabeling, or accidental overdose is possible. Herbs should be purchased from a recognized company or through a qualified herbal practitioner. Herbal practitioners recommend a dose based on a woman's history, body size, lifestyle, diet, and reported symptoms. Women who choose to take herbs for menopausal symptoms should learn as much as possible about herbs and work with a qualified practitioner such as an herbalist, a traditional Chinese doctor, or a naturopathic physician.

The following list of herbs include those that herbalists recommend to treat menopausal symptoms:

- black cohosh (*Cimicifuga racemosa*): hot flashes and other menstrual complaints
- black currant (*Ribes migrum*): breast tenderness
- chaste tree/chasteberry (*Vitex agnus-castus*): hot flashes, excessive menstrual bleeding, moodiness
- chickweed (*Stellaria media*): hot flashes
- evening primrose oil (*Oenothera biennis*): mood swings, irritability, breast tenderness
- fennel (*Foeniculum vulgare*): hot flashes, digestive gas, bloating
- flaxseed (*Linum usitatissimum*): excessive menstrual bleeding, breast tenderness, and other symptoms, including dry skin and vaginal dryness
- ginkgo (*Ginkgo biloba*): memory problems
- ginseng (*Panax ginseng*): hot flashes, fatigue, vaginal thinning
- hawthorn (*Crataegus laevigata*): memory problems, fuzzy thinking
- horsetail (*Equisetum arvense*): osteoporosis
- lady's mantle (*Alchemilla vulgaris*): excessive menstrual bleeding
- licorice (*Glycyrrhiza glabra*) root: general menopausal symptoms
- Mexican wild yam (*Dioscorea villosa*) root: vaginal dryness, hot flashes, general menopause symptoms
- motherwort (*Leonurus cardiaca*): night sweats, hot flashes
- oat straw (*Avena sativa*): mood swings, anxiety
- passionflower (*Passiflora incarnata*): insomnia, pain
- raspberry leaf (*Rubus idaeus*): normalizes hormonal system
- sage (*Salvia officinalis*): mood swings, headaches, night sweats
- skullcap (*Scutellaria lateriflora*): insomnia

WWW.BOOKBAZ.IR

- sesame oil (*Sesamum orientale*): vaginal dryness (applied topically)
- valerian (*Valeriana officinalis*): insomnia
- violet (*Viola odorata*): hot flashes.

Natural estrogens (phytoestrogens)

Phytoestrogens are estrogen compounds found in plants. Proponents of plant estrogens (including soy products) believe that plant estrogens are better than synthetic estrogens, but science has not yet proved this. The results of small preliminary trials suggest that the estrogen compounds in soy products (soy is very high in plant estrogens) can relieve the severity of hot flashes and lower **cholesterol**. In one study at Bowman-Gray Medical School in North Carolina, women were able to ease their menopausal symptoms such as hot flashes by eating a large amount of fruits, vegetables, and whole grains, together with 4 ounces of tofu four times a week. However, no one has shown that plant estrogens can provide these benefits without causing the same negative side effects as estrogen replacement therapy. In addition, it is difficult to judge how much estrogen is in various plant products as there is no requirement for standardization. Many women believe that natural or plant-based means harmless. In large doses, phytoestrogens can promote the abnormal growth of cells in the uterine lining. Unopposed estrogen of any type can lead to an increased risk of cancer.

Several studies have shown that a black cohosh extract (Remifemin) relieved menopausal symptoms as well as or better than estrogen and that it showed the greatest promise among alternative treatments. In a 2007 study conducted at the University of Pennsylvania and published in *International Journal of Cancer*, Remifemin was also shown to reduce the risk of **breast cancer**. The United States Office of Dietary Supplements considers the evidence from studies of black cohosh promising but cautions that the long-term safety of this herb has not been established and recommends that if women choose to use black cohosh extract, they do so for no more than six months.

Flaxseed is also a good source of phytoestrogens. Other sources include red clover leaf, licorice, wild yam, chickpeas, pinto beans, lima beans, and pomegranates. In 2003, red clover leaf was thought to offer relief for hot flashes, but in two short clinical trials, it failed to demonstrate hot flash relief.

Homeopathy

Women interested in homeopathic remedies for menopausal symptoms should consult a homeopathic physician. The following homeopathic remedies are often recommended to alleviate specific groups of symptoms:

- lachesis: hot flashes, irritability, talkativeness, tightness around abdomen, dizziness, fainting
- sepia: bleeding between periods, chilliness, tearfulness, withdrawal from loved ones, sinking feeling in stomach
- pulsatilla: tearfulness, thirstless, feels better with others, avoids heat, hot flashes, varicose veins, hemorrhoids
- sulfur: philosophical personality, feeling hot, itching and burning of vagina and rectum
- lycopodium: low self esteem, bloated after eating, infrequent menstruation, low blood sugar, weak digestion, belching
- *Argentum nitricum:* gas, indigestion, craving for sweets and chocolate, panic attacks, fear of crossing bridges
- Magnesium phosphoricum: severe cramping
- transitional formula: hot flashes, night sweats, insomnia, skin-crawling sensation
- women's formula: perimenopause, PMS, irregular cycles, infertility, absent or excessive bleeding, menopausal discomfort
- vital formula: anxiety, headaches, palpitations, PMS, mood swings

Yoga

Many women find that **yoga** can ease menopausal symptoms. Yoga focuses on helping women unite the mind, body, and spirit to create balance. Because yoga has been shown to balance the endocrine system, some experts believe it may affect hormone-related problems. Studies have found that yoga can reduce **stress**, improve mood, boost a sluggish metabolism, and slow the heart rate. Specific yoga positions deal with particular problems, such as hot flashes, mood swings, vaginal and urinary problems, and other pains.

Exercise

Exercise helps ease hot flashes by lowering the amount of circulating FSH and by raising endorphin levels (which drop during a hot flash). Even exercising 20 minutes three times a week can significantly reduce hot flashes. Weight bearing exercises help to prevent osteoporosis. Regular exercise also provides many health benefits unrelated to menopause.

Acupuncture

This ancient Asian art involves placing very thin needles into different parts of the body to stimulate the system and unblock energy. It is usually painless and has been used for many menopausal symptoms including **insomnia**, hot flashes, and irregular periods. Practitioners believe that **acupuncture** can facilitate the opening of blocked energy channels, allowing the life force energy (chi) to flow freely. This allows the menopausal woman to keep her energy moving. Blocked energy usually increases the symptoms of menopause.

Acupressure and massage

Therapeutic massage involving **acupressure** can bring relief from a wide range of menopause symptoms by placing finger pressure at the same meridian points on the body that are used in acupuncture. There are more than 80 different types of massage, including foot **reflexology**, **Shiatsu** massage, and Swedish massage, but they all are based on the idea that boosting the circulation of blood and lymph benefits health. Breast massage (rubbing castor oil or olive oil on the breasts for five minutes three times a week) is claimed to help balance hormone levels, help the uterus contract during menstruation, and prevents cramping pains.

Biofeedback

Some women have been able to control hot flashes through **biofeedback**, a painless technique that helps a person train her mind to control her body. A biofeedback machine provides information about body processes (such as heart rate) as the woman relaxes her body. Using this technique, it is possible to control the body's temperature, heart rate, and breathing.

Other treatments

Therapeutic touch, an energy-based practice, may relieve menopausal symptoms. Cold compresses on the face and neck can ease hot flashes. Sound or **music therapy** may relieve stress and other menopausal symptoms. Prayer or **meditation** can help improve coping ability.

Dietary supplements

Women should discuss the use of dietary supplements with their healthcare provider. Some supplements interfere with the action of traditional pharmaceuticals and herbal remedies. Other supplements are harmful in large quantities. Supplementation with calcium, **vitamin D**, **vitamin K**, boron, manganese, magnesium, and phosphorous may aid in preventing osteoporosis. **Vitamin E** supplementation may reduce hot flashes and risk of **heart disease**.

Hormone replacement therapy

When a woman enters menopause, her levels of estrogen drop and symptoms, such as hot flashes and vaginal dryness, begin. Before 2002, many physicians treated these symptoms with **hormone replacement therapy** (HRT). HRT treats these symptoms by increasing estrogen and progesterone levels enough to suppress symptoms. However, in the summer of 2002, preliminary results from a large Women's Health Initiative study were released that showed HRT could have significantly harmful effects (harmful enough that the study was stopped early). The study found that a combination of estrogen and progestin (a form of progesterone) HRT caused the following when compared to a placebo (no hormones):

- increased risk of heart attack, stroke, and blood clots
- increased risk of invasive breast cancer
- increased risk of dementia
- decreased risk of colorectal cancer
- decreased risk of bone fractures

Treatment with estrogen alone produced the following results:

- no change in the risk of heart attacks
- increased risk of stroke and blood clots
- unclear changes in the risk of breast cancer
- no change in the risk of colorectal cancer
- decreased risk of bone fractures
- no data available on changes in risk of dementia

At the time the results of the Women's Health Initiative became available, about 9 million American women were using HRT. Most physicians now no longer routinely recommend HRT to treat menopausal symptoms. Nevertheless, under certain circumstances when symptoms associated with menopause are so severe as to interfere with activities of daily life, a short course of HRT may be prescribed. Some doctors believe that short-term use of estrogen for those women with severe symptoms of hot flashes or night sweats is a sensible choice as long as they do not have a history of breast cancer. However, other doctors believe that in almost all cases the risks of HRT outweigh the benefits. The decision should be made by a woman and her doctor after taking into consideration her medical history and situation. Women who choose to take hormones should have an annual mammogram, breast exam, and **pelvic exam** and should report any unusual vaginal bleeding or spotting (a sign of possible uterine cancer).

KEY TERMS

Endometrium—The lining of the uterus that is shed with each menstrual period.

Estrogen—Female hormone produced by the ovaries and released by the follicles as they mature. Responsible for female sexual characteristics, estrogen stimulates and triggers a response from at least 300 tissues, and may help some types of breast cancer to grow. After menopause, the production of the hormone gradually stops.

Follicle-stimulating hormone (FSH)—The pituitary hormone that stimulates the ovary to mature egg capsules (follicles). It is linked with rising estrogen production throughout the cycle. An elevated FSH (above 40) indicates menopause.

Hormone—A chemical messenger secreted by a gland that is released into the blood and that travels to distant cells where it exerts an effect.

Hormone replacement therapy (HRT)—The use of estrogen and progesterone to replace hormones that the ovary no longer supplies. HRT is no longer used as long-term therapy for postmenopausal women.

Hot flash—A wave of heat that is one of the most common perimenopausal symptoms, triggered by the hypothalamus' response to estrogen withdrawal.

Hysterectomy—Surgical removal of the uterus.

Ovary—One of the two almond-shaped glands in the female reproductive system responsible for producing eggs and the hormones estrogen and progesterone.

Phytoestrogen—An estrogen-like substance produced by plants.

Placebo—A pill or liquid given during the study of a drug or dietary supplement that contains no medication or active ingredient. Usually study participants do not know if they are receiving a pill containing the drug or an identical-appearing placebo.

Progesterone—The hormone that is produced by the ovary after ovulation to prepare the uterine lining for a fertilized egg.

Testosterone—Male hormone produced by the testes and (in small amounts) in the ovaries. Testosterone is responsible for some masculine secondary sex characteristics such as growth of body hair and deepening voice.

Uterus—The female reproductive organ that contains and nourishes a fetus from implantation until birth. Also known as the womb.

Postmenopausal treatment for osteoporosis

Raloxifene (Evista, Keoxifene) is a drug that is used to treat osteoporosis (bone loss) in postmenopausal women. It does not increase the risk breast cancer, although it may increase breast tenderness. It may also worsen hot flashes and cause uterine bleeding. It is not a treatment for symptoms associated with menopause. Several other drugs are also available to help reduce the risk of **fractures** in postmenopausal women with osteoporosis. In 2002, the FDA approved teriparatide (Forteo) for the treatment of osteoporosis. Ibandronate (Boniva) and alendronate (Fosamax) are also used to treat osteoporosis in postmenopausal women.

Testosterone replacement

The ovaries also produce a small amount of male hormones (about 300 micrograms), which decrease slightly as a woman enters menopause. Most women never need testosterone replacement. Testosterone can improve the libido and decrease **anxiety** and depression. Adding testosterone is especially beneficial to women who have had hysterectomies. Testosterone also eases breast tenderness and helps prevent bone loss. Side effects include mild **acne** and some facial hair growth.

Results

Menopause is a natural condition of aging. Some women experience no problems associated with menopause, while others notice significant unpleasant symptoms. Results of allopathic and alternative treatments vary from one woman to another.

Prevention

Because menopause is a natural part of the aging process it cannot be prevented, however, some of the symptoms can be relieved by the treatments listed above.

Men's health

Definition

Men's health is concerned with identifying, preventing, and treating conditions that are most common or specific to men.

Overview

Men live about five years less than women; the life expectancy in the U.S. is 76 years for men and 80.9 years for women. The reasons for this discrepancy are not completely understood. Men may have some genetic predisposition for lower life expectancy, as women tend to outlive men in most areas throughout the world. But men also have different lifestyle patterns that increase the wear and tear on their bodies. Studies have shown that men tend to drink and smoke more than women, men obtain medical care less frequently than women, and men generally have more stressful habits. It is clear to health professionals that men can benefit from increased knowledge of male medical issues and by understanding how lifestyle choices impact health.

According to the Centers for Disease Control (CDC), the 10 leading causes of death for men in the United States are:

1. heart disease
2. cancer
3. stroke
4. accidents
5. lung disease (including emphysema and chronic bronchitis)
6. pneumonia
7. diabetes
8. suicide
9. liver disease
10. homicides

Men can experience conditions as diverse as sexually transmitted diseases (STDs), mental illness, arthritis, urinary tract infections, athletic injuries, hair and skin problems, and digestive disorders. The field of men's health strives to reduce the risks and incidence of men's conditions by researching preventive practices, designing testing procedures for early detection, and recommending specialized courses of treatment.

Description

Prevention

Preventive practices for men's health emphasize diet, **exercise** and **stress** management, as well as elimination of risky behaviors such as **smoking** and excessive drinking. Four of the leading causes of death for American men are related to diet—heart disease, cancer, **stroke**, and diabetes. In addition, men are more likely than women to have diet-related conditions, including high **cholesterol**, high blood pressure, and

VIAGRA

Viagra pills. *(AP Images.)*

Erectile dysfunction, the inability to get an erection when aroused, has been a source of frustration and embarrassment for men for hundreds of years. While many herbal and natural remedies have been suggested, until 1983 the majority of scientists believed that erectile dysfunction was largely a psychological problem and should be treated as such. In 1983, however, the first successful injectable treatment for erectile dysfunction was demonstrated.

While injectable treatments for erectile dysfunction were a positive step, they had drawbacks. First, the injection had to be made directly into the penis, something many men were reluctant to try. Second, the injection created an erection very quickly, whether or not the man was mentally aroused or expected to engage in sexual activity.

Sildenafil citrate, marketed as Viagra, was developed by scientists at the Pfizer pharmaceuticals laboratories in Sandwich, England, in 1989. Credit for the drug goes to the Pfizer team of David Brown, Nicholas Terrett, and Andrew Bell. Viagra was not originally intended as a medication for erectile dysfunction. Instead, the scientists were attempting to create a medication that would treat high blood pressure and heart disease.

Clinical trials for Viagra began with cardiac patients but were soon stopped as it became clear the drug was not effective. The results of the trial did show, however, that many of the men in the trial who had previously experienced erectile dysfunction experienced erections while taking the drug.

When Viagra enters the bloodstream, it attaches to an enzyme phosphodiesterase5 (PDE5) found primarily in the penis. PDE5 deactivates cyclic guanosine monophosphate (cGMP), a chemical that causes smooth muscles to relax. Viagra bonds with the PDE5, making it unable to deactivate cGMP, thus allowing the cGMP to work on the blood vessels of the penis, relaxing them and allowing blood to flow in, causing an erection when the man becomes aroused. Viagra is an improvement on the injectable methods of treating erectile dysfunction because when a man becomes aroused, the brain sends signals to the penis that lead to the production of cGMP. Thus Viagra is able to help a man achieve an erection when he is aroused but not in the absence of arousal signals sent to the penis.

After noticing its positive effects on erectile dysfunction in the patients in the cardiac trials, Pfizer quickly began clinical trials of Viagra as a medication to treat erectile dysfunction. The U.S. Food and Drug Administration (FDA) took only six months to approve the drug after the application was submitted, providing final approval in March 1998.

Pfizer immediately began advertising the new drug in ads that featured famous American men, including former senator Bob Dole. Between 1998 and 2013, Viagra was prescribed to more than 40 million American men, earning Pfizer billions of dollars.

obesity, all of which increase the risk of certain diseases and premature death. According to the CDC data from 2009 to 2012, 34.6% of men are obese.

For American men, dietary problems are usually not the result of getting too little nourishment but of eating too much fat, sugar, and overall calories. The dietary change most likely to improve the health of males is reduced intake of fats, particularly cholesterol and saturated fats. Cholesterol and saturated fats are found mainly in meat and dairy products. Calories from fat should amount to no more than 30% of total daily calories. Eating adequate protein is generally not a problem for American men, so replacing some dairy and meat consumption with high fiber vegetable proteins such as beans and soy would be beneficial. Complex carbohydrates should provide the bulk of daily calories, such as those from whole grains and legumes, while sugar intake such as in soft

drinks, desserts, and processed foods should be significantly reduced. Increasing dietary fiber is recommended by eating plenty of fresh fruits, vegetables, whole grains, and legumes. Other principles of a healthy diet are avoiding artificial and processed foods, eating food that is as fresh and natural as possible, drinking plenty of water, and avoiding hydrogenated or partially hydrogenated oils, which contain unhealthy substances called trans-fatty acids. Overeating should be avoided as should snacking between meals. Alcohol intake should be limited to one or two glasses per day.

Exercise

The health of men has been affected as work patterns have shifted. Physical labor has been replaced by machines and office work. Studies have estimated that more than 30% of Americans are now obese, which means that nearly one out of three people is significantly overweight. Obesity poses many risks including increased chance of **heart disease**, diabetes, and some cancers. Effective exercise programs help men control weight, reduce stress, increase energy levels, improve self-esteem, reduce **pain** and injuries, and improve sleep. Exercise programs should emphasize flexibility and stretching as well as plenty of aerobic activities, such as running and swimming. These activities exercise the heart and lungs and burn excess calories. Men may also choose anaerobic activities such as weight training to add muscles and increase strength. Routines should begin with warm-ups to reduce the chances of injuries and end with cool-down exercises to speed recovery.

Stress reduction

Stress is a silent killer; chronic (long-term) stress is a risk factor in many of the major diseases affecting men's mortality rates. Prolonged stress may cause **ulcers**, **sleep disorders**, addictions, depression, **anxiety**, and other conditions. Reduction of stress may require changes in both activities and attitudes. Exercise is recommended, as is reducing dependence on alcohol and nicotine. Men with extreme job-related stress may choose to spend more time with their families or in enjoyable activities. Men with stress levels that lead to destructive behaviors may need to pursue **psychotherapy** or significant lifestyle changes. **Nutrition**, social support, and healthy sleep patterns also reduce stress.

Alternative therapies may help with **stress reduction**. Their use has been adopted by many leading health centers. **Biofeedback** utilizes machines that monitor users' stress levels, helping people learn to control them. **Meditation** and other mind/body techniques are taught to enable the relaxation response, which has the opposite effects of stress in the body.

Testing

Routine physical examinations performed by physicians are recommended every three years for men in their twenties and thirties, every two years for men in their forties, and every year for men over 50. Physicians may order several screening tests depending on the age and condition of the patient. Blood tests screen for diabetes, high cholesterol, cancer, infections, and HIV. The prostate-specific antigen (PSA) test is a blood screen for **prostate cancer**. The digital rectal exam is used to manually check the prostate gland for enlargement or irregularities. Urine tests check for infections, kidney problems, and diabetes. The **fecal occult blood test** examines the stool for indications of ulcers or cancer. A **sigmoidoscopy** checks the health of the rectum and lower colon. Electrocardiograms (ECGs) check the status of the heart. Older men should consult an ophthalmologist (eye specialist) every two years for vision and **glaucoma** testing.

Men may perform self-tests as preventative measures. During a **skin cancer** self-exam, the entire skin is checked closely for irregular or changing **moles**, lesions, or blemishes, usually red, white or blue in color. Abnormal findings should be reported to a physician. Like some forms of skin cancer, **testicular cancer** tends to spread rapidly and early detection is crucial. The testicular self-exam is best performed in the shower or bath, because warm water relaxes the scrotum. The testicles are gently rolled and massaged between the fingers and thumb to feel for bumps, swelling, tenderness, or irregularities. Some self-test kits are available in pharmacies, including kits for blood pressure, high cholesterol, colorectal cancer, and blood glucose (diabetes). These do not take the place of proper medical care, and physicians should be consulted before their use.

Heart disease

Heart disease is the major cause of death among men. It claims nearly 600,000 lives each year in the United States and is more likely in men than women. Heart disease can take several forms but the most prevalent is coronary heart disease, in which the blood vessels that supply the heart with oxygen become blocked and the heart muscle becomes increasingly stressed. Arteriosclerosis, a major factor, is the hardening of arteries due to the accumulation of

WWW.BOOKBAZ.IR

fatty materials. **Hypertension**, or high blood pressure, also poses major risks for both heart disease and stroke. A study released in 2013 found a potential link between testosterone therapy in men with **low testosterone** levels and **heart attack** and stroke.

Angina pectoris is the chest pain associated with the early stages of heart disease; it affects more than three million American men. When the blockage of blood supply to the heart becomes severe, a myocardial infarction (heart attack) may occur, which can be fatal.

The main symptom of angina pectoris is sharp pain on the left side of the chest that may radiate throughout the upper body. Other symptoms include **shortness of breath**, **dizziness**, **fatigue**, and swelling in the legs and ankles. Angina may be triggered by physical or emotional stress and lasts up to 30 minutes. Heart attacks have similar symptoms but with longer and more intense pain in the chest and upper body and may be accompanied by cold sweats and **vomiting**.

The American Heart Association lists the main risk factors for heart disease as being male, old age, having family history of the disease, smoking, high cholesterol, high blood pressure, diabetes, **alcoholism**, obesity, physical inactivity, and stress. Lifestyle habits such as diet, exercise and stress control play major roles in the development and prevention of heart disease in men.

Osteoporosis

Osteoporosis is a disease characterized by a decrease in bone mass and density. Often thought of as more prevalent in women, more than two million men have the disease. It develops about 10 to 15 years later in life in men than in women and risk of **fractures** from the disease can be greater in men. Men can decrease their risk by increasing **calcium** and **vitamin D**.

Cancer

The American Cancer Society (ACS) estimates that more than 1.6 million cases of cancer were reported in 2012, not including the basal and squamous cell skin cancers. Men have a slightly higher risk for cancer than women. The World Health Organization (WHO) estimates that the number of cancer cases in most countries will double in the next 25 years, while men's prostate cancer is expected to go up 40% worldwide. The most common cancers in men are prostate, bladder and kidney, lung, colon, skin, lymphoma (lymph glands), oral (mouth and throat), and testicular cancer. The ACS lists seven warning signs of cancer:

- unusual bleeding or discharge
- changes in bowel or bladder patterns
- persistent sores
- lumps or irregularities on the body
- difficulty swallowing or indigestion
- changes in warts or moles
- persistent cough or hoarseness in the throat

Although the causes of cancer are incompletely understood, there are several risk factors that increase its chances: family history of cancer, smoking, poor diet (high in fat, low in fiber), excessive alcohol consumption, skin damage from sunlight, and exposure to radiation, chemicals, and environmental pollutants.

The prostate gland is a walnut-sized organ in the male reproductive system, located near the rectum below the bladder. The ACS reported that nearly 241,000 new cases of prostate cancer would be diagnosed in 2012, causing more than 28,000 deaths, making prostate cancer the second most fatal cancer for men behind lung cancer. Worldwide studies have shown that about 12% of men in Western countries get prostate cancer, while 50% have enlarged prostates. Benign prostatic hyperplasia (BPH) is the enlargement of the prostate gland, called benign when it is noncancerous although growth can be rapid.

With early detection, 98% of men with prostate cancer survive for five years. Symptoms of prostate cancer include difficulty in stopping or starting urination, frequent nighttime urination (nocturia), weak urine flow, and blood in the urine or semen. A PSA (prostate specific antigen) test has been used to screen for prostate cancer but the test is controversial because the test may elicit false positive results, leading to biopsies, sometimes with complications, for men who do not have prostate cancer. A study published in 2014 suggested that men discuss the pros and cons of this test with their healthcare provider.

Testicular cancer is most common in men between the ages of 15 and 34. The ACS estimated that there would be about 8,600 new cases of testicular cancer in 2012 in the United States. Cigarette smoking increases the risk of testicular cancer but quitting smoking does not reduce the risk.

Stroke

Strokes occur when the blood supply to the brain is interrupted and brain function becomes impaired due to lack of oxygen. Ischemic strokes occur due to blood vessels becoming blocked while hemorrhagic

strokes are the result of broken blood vessels in or near the brain. Ischemic strokes account for about 80% of all strokes. The Centers for Disease Control and Prevention estimates that more than 795,000 Americans have strokes each year, with men having a 20% higher risk of stroke than women, although more women die from strokes. Other risk factors are hypertension (high blood pressure), previous heart attacks, age, **atrial fibrillation**, family history, high cholesterol, smoking, obesity, alcoholism, and physical inactivity. African Americans have nearly twice the risk for stroke than whites.

Symptoms of strokes include sudden weakness or numbness, blurring or loss of vision, difficulty speaking or understanding, sudden severe **headache**, and dizziness or falling. Stroke victims should receive immediate emergency care.

Diabetes mellitus

Carbohydrate intolerance—the inability to properly metabolize sugars—is known as **diabetes mellitus**, often just shortened to diabetes. The pancreas makes insulin, a hormone responsible for a cell's uptake of glucose (sugar) from blood for energy. People who have diabetes do not make enough insulin, or else the body cannot use what is made. Treatment includes achieving a healthy weight, engaging in exercise, and taking prescription medication. Sometimes people are able to cure their diabetes with diet and weight loss.

A proper diet for people with diabetes is comparable to what the average healthy person should already be eating. Basic tenets include: eat three meals daily, incorporate healthful snacks, focus on foods high in fiber, combine protein and carbohydrates with moderate amounts of unsaturated fat, and avoid sugar-sweetened beverages to reduce overall caloric intake.

Male urinary tract problems

The urinary system includes the kidneys and bladder, the ureters between the kidneys and bladder, and the urethra, the tube through which urine flows from the bladder. Symptoms of urinary tract problems include frequent urination, excessive urination at night, painful or burning urination, weak urination, blood in the urine, or incontinence (involuntary loss of urine). **Urethritis** is infection of the urethra, which is a major symptom of sexually transmitted diseases (STDs). **Kidney stones** (nephrolithiasis) are the most common urinary tract problems, accounting for nearly one out of every 100 hospital admissions in the United States. Eighty percent of kidney stone patients are men. About 12% of American men develop kidney stones during their lifetimes. Kidney stones cause extreme pain when they move from the kidneys into the ureters. Ten percent of kidney stone cases require surgery. The best prevention for kidney stones is drinking plenty of fluids daily.

The male reproductive system

The male reproductive system includes the penis, testicles, scrotum, prostate, and other organs. Problems include **orchitis**, or infection of the testicles, and hydrocele, the buildup of fluid on the testicles. **Epididymitis** is inflammation of the tube that transports sperm from the testicles, and can cause severe pain, swelling, and **fever**. A varicocele is a group of **varicose veins** in the scrotum that can cause swelling and damage sperm. Peyronie's disease is the abnormal curvature of the penis caused by accumulated scar tissue. **Testicular torsion** is considered a medical emergency, when a testicle becomes twisted and blood supply is cut off. This condition can lead to permanent damage if not treated quickly. It is most common in males between the ages of 12 and 18. **Prostatitis** is infection or inflammation of the prostate gland.

Sexually transmitted diseases include **genital warts**, chlamydia, **gonorrhea**, **syphilis**, **genital herpes**, hepatitis, and HIV (human **immunodeficiency** virus). HIV is the leading cause of death for American men between the ages of 25 and 45. Symptoms of STDs include discharge of fluid from the penis; painful urination; sores, lesions, **itching**, or **rashes** in the genital area; and swelling of the lymph nodes in the groin. A study released in 2014 showed that syphilis cases in men were increasing.

Prevention of STDs begins with safe sexual behavior: wearing **condoms**, limiting the number of sexual partners, not mixing sexual encounters with alcohol, and avoiding sexual contact with infected people, prostitutes, and intravenous drug users. Men who engage in risky behaviors should have frequent **HIV tests** and medical examinations.

Male sexual health

Erectile dysfunction (ED), also called **impotence**, is a man's inability to maintain an erection for sexual intercourse. It affects nearly one in every 10 American men. Incidence of ED increases with age, but the problem can occur at any age. Up to 80% of ED is caused by physical problems, while 20% of cases are psychogenic, or psychological in origin. Causes of ED include hormonal problems, injuries, nerve damage,

WWW.BOOKBAZ.IR

diseases, infections, diabetes, stress, depression, anxiety, drug abuse, and interactions with prescription drugs. ED may be the first indication of circulation problems due to diabetes, high blood pressure, or **coronary artery disease**.

A self-test men can perform to determine whether ED is physical or psychological is the stamp test, or nocturnal penile tumescence test. Physically healthy men experience several prolonged erections during sleep. The stamp test is done by attaching a strip of stamps around the penis before bedtime; if the stamps are torn in the morning, it generally indicates that nocturnal (nightly) erections have occurred and thus ED is not physiological. Men with ED should see a urologist for further diagnosis and discussion of the several treatment options available including drugs, hormone injections, and surgical repair or implants. Several new prescription drugs have been produced.

Other types of **sexual dysfunction** include **premature ejaculation**, in which men cannot sustain intercourse long enough to bring their partners to climax, and retarded ejaculation (also called male orgasmic disorder) when male orgasm becomes difficult. Some men have periods of inadequate sexual desire (**hypoactive sexual desire disorder**), while sexual aversion disorder (SAD) is fear and repulsion of sexual activity. **Dyspareunia** is painful intercourse and should be reported to physicians as it may indicate STDs or infections. In addition to medical care, sexual dysfunction may be treated by **sex therapy** or psychotherapy depending on its causes.

Circumcision is the surgical removal of the foreskin of the penis, for religious and medical reasons, performed on 60% of newborn males in the United States. Increasing controversy surrounds this procedure. Advocates of circumcision claim it prevents infections (called **balanitis**) on the head of the penis and reduces chances of **penile cancer**. Opponents of circumcision claim that the outdated procedure affords no medical benefits, causes unnecessary pain for infants, and that the lack of a foreskin may reduce sexual pleasure and performance.

Family planning

Infertility occurs when men lack an adequate supply of sperm to cause **pregnancy**. As many as 15% of American couples, or more than five million Americans, are affected by infertility in one or both partners. A WHO project found that in about 20% of infertile couples, the problem was due to the man, while in another 27% of couples both partners had infertility problems. Injuries, **birth defects**, infections, environmental pollutants, chronic stress, drug abuse, and hormonal problems may account for male infertility, while one in four cases has no apparent cause and is termed idiopathic infertility. Declining sperm counts have been observed in industrialized countries, and possible explanations for this decrease are as diverse as increased environmental pollutants to the use of plastic diapers, which a German study claims damages infant testicles by keeping in excess heat. Male infertility can be diagnosed by sperm analysis, blood tests, radiographic scans of the testicles, and other tests.

Vasectomies, a form of male birth control, are surgical operations that sever the tubes that transport sperm from the testicles. Vasectomies can be reversed but 10% of men become infertile due to the surgery. Another form of male birth control is the condom, which is the most effective at preventing sexually transmitted diseases.

Men's emotional health

Depression is a mood disorder marked by sadness, emotional pain, and the inability to feel pleasure. At least 10% of men will experience an episode of major depression at least once in their lives. Men with depression are five times more likely to commit **suicide**, a major cause of mortality in men. Men are half as likely as women to seek psychological help. Men may experience depression and emotional problems between the ages of 50 and 65, called the midlife crisis, as men face the major transition into retirement and older age.

Panic attacks have symptoms of overwhelming fear, chest pain, shortness of breath, numbness, and increased heart rate. Men may mistake them as heart attacks. Men also are plagued by addictions to nicotine, alcohol, and other drugs, which are often the unhealthy escape routes from deeper emotional issues. Studies have estimated that as many as one-third of Americans have sleep disorders, which may be psychological in origin and related to anxiety, stress, and lifestyle.

Mental illness can be particularly difficult for men because men are taught to withhold rather than express emotions and feelings. Emotional problems can be strong signals for men to communicate and confront deeper issues. Help can be found from physicians, psychotherapists, and spiritual or religious counselors.

KEY TERMS

Emphysema—Disease of severe lung deterioration and impairment.

Obesity—Condition defined as being overweight by 30% of normal limits.

Sigmoidoscopy—Test procedure using an optical instrument to view the internal rectum and colon.

Urologist—Physician specializing in male reproductive and urinary systems.

Men's nutrition

Definition

Men's **nutrition** addresses the dietary requirements of males after they reach adulthood. Nutritional needs change over time due to factors such as **aging** and physical activity levels.

Purpose

Men's nutrition focuses on foods that help to promote health and prevent the risk of chronic diseases. A nutritious diet and regular physical activity are part of a healthy lifestyle that helps prevent the risk of developing diseases such as type 2 diabetes, high blood pressure (**hypertension**), high **cholesterol**, cardiovascular disease, and certain cancers.

Description

As a man ages, changes in the body occur that affect nutritional needs. After age 25, the basal metabolic rate (BMR) begins to decline. Metabolism is the process of the body converting food into energy. When metabolism slows, the body needs fewer calories to function. If calorie intake is not adjusted or if additional calories are not expended through physical activity, the resulting imbalance causes weight gain. Continued weight gain further slows the BMR, reducing overall calorie requirements.

The BMR is based on factors, including size and particularly muscle mass. People who are larger or have more muscles use more calories than those who are smaller or have less muscle mass. Muscle mass tends to decline with age—after age 30, muscle mass decline occurs at a rate of 3%–8% or more per decade. This decrease in muscle mass is a factor in BMR decline. Failure to **exercise** muscles can result in a

WWW.BOOKBAZ.IR

loss of 30%–40% of muscle strength by the time a person is 65. Muscle loss can be reduced through regular strength training and daily intake of dietary proteins such as lean meat, fish, chicken, or soy products.

Eating a balanced diet promotes wellness and disease prevention. Men may fall short of achieving a healthy diet due to busy work schedules, fear of or disinterest in cooking, and stresses of daily living. Nutrition is also affected by attitudes, situations, and choices made about diet and physical activity. According to the U.S. Department of Agriculture (USDA) and the Department of Health and Human Services (HHS), the top 10 sources of calories for adults in the United States in 2010 were:

- grain-based desserts
- yeast breads
- chicken and chicken mixed dishes (usually fried)
- soda, power drinks, and sports drinks
- alcoholic beverages
- pizza
- tortillas, burritos, and tacos
- pasta and pasta dishes
- beef and beef mixed dishes
- dairy desserts

The USDA and HHS encourage regular consumption of fruits and vegetables, lean proteins and dairy, and whole grains, with foods like desserts, fast food, and soda to be consumed only on occasion.

MyPlate

The USDA's *Dietary Guidelines for Americans* is a guide to a nutritionally balanced eating plan. The guidelines are represented by MyPlate, a graphic representation of the general daily recommendations for the five food groups. The graphic is of a plate divided into four sections—on one half are fruits and vegetables and on the other half are grains and proteins. To the side is a small circle representing dairy products.

Some of the MyPlate guidelines include:

- Fill half of each plate with fruits and vegetables. Recommended choices include red, orange, and dark-green vegetables such as tomatoes, sweet potatoes, and broccoli.
- Cut back on foods high in solid fats, added sugars, and sodium (salt).
- Vary protein food choices and keep meat and poultry portions small and lean. Beans are another good source of protein. People are advised to eat seafood at least twice a week, especially varieties that contain omega-3 fatty acids (such as salmon and tuna).
- Make half of all grains consumed whole grains. Examples include 100% whole-grain cereals, breads, crackers, rice, and pasta.
- Drink skim or 1% milk. These products have the same amount of calcium and other essential nutrients as whole milk but contain less fat and calories. Calcium-fortified soy products are another alternative.

Calorie recommendations

Daily calorie requirements depend upon how active a person is, according to the *Dietary Guidelines*. The USDA provides general calorie recommendations for men based on age and activity level.

Men between the ages of 19 and 30 should consume approximately:

- between 2,400–2,600 calories if sedentary
- between 2,600–2,800 calories if moderately active
- 3,000 calories if regularly active

Men between the ages of 31 and 50 should consume approximately:

- 2,200–2,400 calories if sedentary
- 2,400–2,600 calories if moderately active
- 2,800–3,000 calories if regularly active

Men 51 or older should consume:

- 2,000–2,200 calories if sedentary
- 2,200–2,400 calories if moderately active
- 2,400 and 2,800 calories if regularly active

Macronutrients

All dietary calories come from macronutrients—carbohydrates, fats, and proteins. Macronutrients are dietary compounds that provide energy. Proteins and carbohydrates contain four calories per gram, and fat contains nine calories per gram. Alcohol is also considered a macronutrient and contains seven calories per gram. Carbohydrates serve as the primary source of fuel for the body. When food is consumed, the sugars and starch in carbohydrates are used (as glucose) for energy. Excess glucose is stored in the muscles as glycogen. If the glycogen reserves are not used, they are converted to fat, resulting in weight gain.

CARBOHYDRATES. Sources of healthy carbohydrates include vegetables, fruits, legumes, and whole grains. Other carbohydrates include sugars, starches, and fiber.

Soluble fiber is found in many vegetables and fruits. Other sources include legumes, barley, oats, and oat bran. Soluble fiber helps to slow digestion so that a person fills full for a longer period of time. This

sense of fullness, known as satiety, helps with appetite control and weight loss. Soluble fiber also helps to decrease cholesterol levels, which lowers the risk for **heart disease**. Insoluble fiber is found in vegetables such as green beans, wheat and other grains, and the skins of vegetables and fruits. This fiber, which is known as roughage, helps to prevent **constipation**.

FATS. Because fats contain more calories than protein or carbohydrates, people should choose healthy fats and consume them in limited amounts. Healthier fats include monounsaturated or polyunsaturated fats. These unsaturated fats help to reduce to blood cholesterol levels. Saturated fats and *trans* fats, on the other hand, promote heart disease if consumed in high amounts.

PROTEIN. Protein is the major functional and structural component of every cell in the body. Proteins are composed of amino acids, nine of which cannot be synthesized to meet the body's needs. These amino acids must be obtained from the diet. Food proteins, known as dietary proteins, include meat, eggs, seafood, beans and peas, nuts, seeds, and soy products. The quality of a source of dietary protein depends on its ability to provide the nitrogen and amino acid requirements needed for growth, maintenance, and repair.

ALCOHOL. Men should limit alcoholic consumption to two drinks per day, according to the *Dietary Guidelines*. Heavy drinking or **binge drinking** can be hazardous to health. According to the Mayo Clinic, examples of one drink include:

- 12 fluid oz. (355 mL) of beer
- 5 fluid oz. (148 mL) of wine
- 1.5 fluid oz. (44 mL) of distilled spirits (80 proof)

Some studies have indicated that regular alcohol consumption may have health benefits, such as a reduced risk of developing heart disease. According to the Mayo Clinic, these benefits may only apply to older men or those with existing risk factors for heart disease, such as high cholesterol. For younger and middle-aged men, the risks of regular alcohol consumption (in excess of recommendations) could outweigh any potential benefits.

Alcohol interacts with many medications and can worsen certain medical conditions.

RECOMMENDED INTAKES. The recommended dietary reference intakes (DRIs) for adults are that 45%–65% of daily calories should come from carbohydrates, 10%–35% from protein, and 20%–35% from fat. People should limit intakes of dietary cholesterol, *trans* fats, and saturated fats. The recommended adequate intake (AI) levels for omega-3 fats are 1.6 grams for men 19 and older; the AI for omega-6 fats is 17 g for men between the ages of 18 and 50 and 14 grams for men age 51 and older.

The AI for fiber is 14 grams per 1,000 calories, or 38 grams per day for men. Most people in the United States do not consume enough dietary fiber, and usual intake averages around only 15 grams per day. To meet the recommendations for fiber, men should increase their consumption of beans and peas, vegetables, fruits, and whole grains. Whole grains can vary in fiber content, so consumers should check the nutrition facts label to find out a product's fiber content.

Vitamins and minerals

The *Dietary Guidelines* identify four nutrients of concern that people in the United States tend to lack, due to low amounts of vegetables, fruits, whole grains, milk and milk products, and seafood in the "typical" American diet. These nutrients are **calcium**, **vitamin D**, potassium, and dietary fiber.

CALCIUM AND VITAMIN D. Diets low in calcium and vitamin D may increase the chance of developing osteomalacia and **osteoporosis**, characterized by weak or brittle bones. Good nutrition and weight-bearing exercise, such as walking, hiking, or climbing stairs, helps to build and maintain bones.

Good sources of calcium include low-fat dairy products such as cheese, yogurt, and milk; canned fish with bones, such as salmon and sardines; dark green leafy vegetables; and calcium-fortified foods such as orange juice, bread, and cereal. The recommended intake of calcium for men between the ages of 19 and 50 is 1,000 mg per day. Men 71 and older should consume 1,200 mg of calcium per day.

Men can obtain vitamin D in three ways: from sunlight on the skin, from the diet, and from supplements. Experts recommend a daily intake of 600 IU of vitamin D up to age 70. After age 70, men should increase their uptake to 800 IU daily. This can be obtained from supplements or vitamin D-rich foods such as egg yolks, saltwater fish, liver, and fortified milk. The Institute of Medicine, which determines the DRIs, recommends no more than 4,000 IU per day for adults. Doctors may prescribe higher doses if people are deficient in vitamin D.

POTASSIUM AND SODIUM. Dietary potassium can help lower blood pressure by reducing the adverse effects of **sodium**. Other possible benefits of a diet rich in potassium include a reduced risk of developing **kidney stones** and decreased bone loss. The *Dietary Guidelines* recommend that U.S. adults should consume no

more than 2,300 mg of sodium per day. This drops to 1,500 mg per day for people aged 40 or older, people with high blood pressure, and African Americans, who are at higher risk for hypertension. According to the Centers for Disease Control and Prevention, 69% of U.S. adults fall within these categories.

The AI for potassium for adults is 4,700 mg per day. Dietary sources of potassium include bananas, white beans, plain yogurt, baked potatoes, and clams.

Precautions

Dietary risk factors involved in the cause or prevention of heart disease include dietary **antioxidants**, fiber, and fat. Antioxidants are non nutrient compounds in foods that protect the body's cells from damage. They are found in fruits and vegetables. Soluble fiber, such as the fiber in oatmeal, helps to lower blood cholesterol levels, whereas cholesterol levels rise in response to diets high in total fat and/or saturated fat. A high level of cholesterol in the blood is a risk factor for heart disease, as is hypertension. Weight control, an active lifestyle, and a diet low in salt and fat and high in fruits and vegetables may help to prevent hypertension.

Men should consult with a physician before starting a new diet or exercise program.

Complications

An unhealthy diet and physical inactivity are linked to numerous preventable conditions including **obesity**, high blood pressure, heart disease, diabetes, and certain cancers.

Obesity and overweight

Obesity is considered an epidemic in the United States that affects all age groups. According to the U.S. Centers for Disease Control and Prevention (CDC), 35.7% of adults aged 20 and older were obese in 2009–2010, which accounted for more than 37 million men and almost 41 million women.

Obesity is defined as an abnormal accumulation of body fat. It is usually determined by the **body mass index** (BMI), a measurement for adults based on height and weight. A BMI of 18.5–24.9 is considered normal weight, 25–29.9 is considered overweight, and 30 or higher is obese.

Another measure of health risk is waist size. Abdominal weight, also known as belly fat, places people at risk for conditions such as high blood pressure, type 2 diabetes, and heart disease. For men, these risks increase when the waist measurement is greater than 40 in. (102 cm).

Hypertension

According to the CDC, 64% of men aged 75 and older have hypertension (high blood pressure) in the United States, and African Americans are at a greater risk. Termed the "silent killer," hypertension often has no physical symptoms. Men often feel well enough to function normally in their day-to-day lives, and they do not view the risk as a serious one.

Being obese is associated with hypertension, and losing weight often helps to control blood pressure. Additionally, some men are sensitive to sodium. Eating too much salt can cause the body to retain water, resulting in increased blood pressure. Processed foods tend to be high in salt.

Heart disease

Heart disease, or coronary heart disease, is a result of improper function of the heart and blood vessels. There are many forms of heart disease. Atherosclerosis (hardening of the arteries) is one of the most common. Fat deposits disrupt the flow of blood to the heart muscle, increasing the risk of myocardial infarction (**heart attack**).

Heart disease is the number one cause of death for men in the United States. According to the American Heart Association (as reported in 2012), more than one in three adult men have some form of cardiovascular disease (CVD). In 2008, 392,210 men died from CVD.

Other risk factors for CVD include being 45 years of age and older, low levels of high-density lipoprotein (HDL, or "good" cholesterol), high levels of low-density lipoprotein (LDL, or "bad" cholesterol), hypertension, **smoking**, obesity, diabetes, and a family history of heart disease.

The most important step men should take to prevent heart disease is to quit smoking (if they smoke) and manage their weight. Dietitians recommend including lean protein in the diet—such as white meat chicken, turkey, and sirloin instead of filet mignon. Additionally, eating fatty fish (e.g., salmon or mackerel) twice a week may have a cardioprotective effect. Baking and broiling cooking methods are preferred over deep frying.

Diabetes mellitus

In 2011, 13 million men in the Unites States (aged 20 or older) had diabetes, according to the American

Diabetes Association. This equated to approximately 11.8% of all men in the United States. Normally, the pancreas makes insulin, the hormone responsible for a cell's uptake of glucose (sugar) from blood for energy. In diabetes, the body either does not produce enough insulin or does not respond to it correctly. There are two types of diabetes—type 1 and type 2. Type 2 diabetes is associated with obesity, and treatment often includes achieving a healthy weight and engaging in exercise. Sometimes prescription medication is needed, but many people are able to manage their diabetes with diet and weight loss.

Cancer

Cancer is characterized as aberrant and uncontrolled cell growth. Cells divide more rapidly than normal, and these growths may metastasize (spread to other organs). It affects people of all ages and can attack any organ or tissue of the body. Some cancers are more responsive to treatment, while others seem to appear suddenly and resist treatment.

Much of what is known from nutritional epidemiology supports the role of diet as a means of cancer prevention. A mostly plant-based diet—one high in fruits, vegetables, and whole grains—is recommended. Men should aim for five to nine servings of fruits and vegetables daily and eat grains that are high in fiber, such as whole-wheat bread, bran flakes, brown rice, and quinoa.

Apart from diet, the most important change a man can make to reduce his cancer risk is cease using tobacco products (or never start). Smoking is the number one preventable cause of death in the United States, claiming over 400,000 lives per year, and it increases the risk for developing cancer. Genetics and environmental sources (such as ultraviolet light) are also linked with cancer.

Other conditions

PROSTATE HEALTH. The prostate is a small gland surrounding the urethra that transports semen. The CDC reported that 223,307 men in the United States were diagnosed with **prostate cancer** in 2007, and 29,093 men died of prostate cancer. Signs of prostate trouble are weak urine flow and dribbling and incontinence (inability to control urinary bladder). One risk factor for prostate cancer is abdominal obesity.

IMPOTENCE. **Impotence**, also known as **erectile dysfunction**, occurs when a man cannot maintain an erection to achieve orgasm in sexual intercourse. The National Institutes of Health reports that as many as 30 million men in the United States are affected by erectile dysfunction. In addition, about 4% of men in their fifties and almost 17% of men in their sixties have a total inability to have an erection. For men older than 75, the statistic climbs to 46%.

Many conditions can prevent normal erection, including psychological interference, neurological problems, abnormal blood flow, and prescription medications. Certain health conditions, such as diabetes and heart disease, can also contribute to impotence.

OSTEOPOROSIS. When a man is in his twenties, he continues to build bone density (thickness). Calcium intake during these years will help protect against bone loss later in life. Bone density starts to naturally decrease when a man is in his forties. Bone loss could be accompanied by a loss in bone strength and increased risk of osteoporosis, a condition described as "brittle bones." Although generally associated with

KEY TERMS

Adequate intake (AI)—Recommendations for vitamins and minerals that are established when there is not enough evidence to determine an RDA.

Body mass index (BMI)—Determines whether a person is at a healthy weight, underweight, overweight, or obese. BMI is calculated by squaring height (in inches) and dividing by weight, then multiplying that number by 703. The metric formula for the BMI is the weight in kilograms divided by the square of height in meters.

Erectile dysfunction—The inability to get or maintain an erection.

Hypertension—High blood pressure.

Osteomalacia—A softening of bones caused by a lack of vitamin D and/or calcium in the diet or the malabsorption of these vitamins in the body.

Osteoporosis—Thinning of the bones with reduction in bone mass due to depletion of calcium and bone protein. Osteoporosis predisposes a person to fractures, which are often slow to heal and heal poorly. It is more common in older adults.

Recommended dietary allowance (RDA)—The average daily dietary intake level that is sufficient to meet the nutrient requirements of nearly all (approximately 98%) healthy individuals.

Type 2 diabetes—Type of diabetes in which the pancreas either does not make enough insulin or cells become insulin resistant and do not use insulin efficiently.

women, men are also susceptible to osteoporosis, according to the American Academy of Orthopaedic Surgeons (AAOS). Men most likely to be diagnosed with this condition are 76 or older and have lost more than 5% of their body weight in the previous four years. Other risk factors include physical inactivity and smoking. For both men and women, a diet rich in calcium and regular weight-bearing exercise is key to bone health.

Menstrual disorders

Definition

A menstrual disorder is a physical or emotional problem that interferes with the normal menstrual cycle, causing **pain**, unusually heavy or light bleeding, delayed menarche, or missed periods.

Description

A woman of childbearing age should menstruate every 28 days or so unless she is pregnant or moving into **menopause**. Numerous factors can malfunction with the normal menstrual cycle, some the result of physical causes, others emotional. These include **amenorrhea**, or the cessation of menstruation, menorrhagia, or heavy bleeding, and **dysmenorrhea**, or severe menstrual cramps. Nearly every woman will experience one or more of these menstrual irregularities at some time in her life.

Amenorrhea

There are two types of amenorrhea: primary and secondary. Overall, they affect 2–5% of childbearing women, a number that is considerably higher among female athletes (possibly as high as 66%).

Primary amenorrhea occurs when a girl at least 16 years old is not menstruating. Young girls may not have regular periods for their first year or two, or their periods may be very light, a condition known as **oligomenorrhea**. A light flow is nothing to worry about. But if the period has not begun at all by age 16, there may be something wrong. Amenorrhea is most common in girls who are severely underweight and/or **exercise** intensely, both of which affect the amount of body fat necessary to trigger the release of hormones that, in turn, begin **puberty**.

Secondary amenorrhea occurs in women of childbearing age after a period of normal menstruation and is diagnosed when menstruation has stopped for three months. It can occur in women of any age.

Dysmenorrhea

Characterized by menstrual cramps or painful periods, dysmenorrhea, which comes from the Greek words for "painful flow," affects nearly every woman at some point in her life. It is the most common reproductive problem in women, resulting in numerous days absent from school, work, and other activities. There are two types: primary and secondary.

Primary, or normal cramps, affects up to 90% of all women, usually occurring in women about three years after they start menstruating and continuing through their mid-twenties or until they have a child. About 10% of women who have this type of dysmenorrhea cannot work, attend school, or participate in their normal activities. It may be accompanied by backache, **dizziness**, **headache**, nausea, **vomiting**, **diarrhea**, and tenseness. The symptoms typically start a day or two before menstruation, usually ending when menstruation actually begins.

Secondary dysmenorrhea has an underlying physical cause and primarily affects older women, although it may also occur immediately after a woman begins menstruation.

Menorrhagia

Menorrhagia, or heavy bleeding, most commonly occurs in the years just before menopause or just after women start menstruating. It occurs in 15–20% of American women.

Premenstrual dysphoric disorder (PMDD)

The fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, or DSM-IV, lists **premenstrual dysphoric disorder** (PMDD) in an appendix of criteria sets for further study. To meet full criteria for PMDD, a patient must have at least five out of 11 emotional or physical symptoms during the week preceding the menses for most menstrual cycles over the previous 12 months. Although the DSM-IV definition of PMDD as a mental disorder is controversial because of fear that it could be used to justify prejudice or job discrimination against women,

WWW.BOOKBAZ.IR

there is evidence that a significant proportion of premenopausal women experience emotional distress or impairment in job functioning in the week before their menstrual period. One group of researchers estimates that 3–8% of women of childbearing age meet the strict DSM-IV criteria for PMDD, with another 13–18% having symptoms severe enough to interfere with their normal activities.

Causes and symptoms

Amenorrhea

The only symptom of primary amenorrhea is delayed menstruation. In addition to low body weight or excessive exercise, other causes of primary amenorrhea include Turner's syndrome, a birth defect related to the reproductive system, or ovarian problems. In 2003, a group of researchers reported on a new genetic mutation associated with primary amenorrhea. In secondary amenorrhea, the primary symptom is the ceasing of menstruation for at least three months. Causes include **pregnancy** or **breastfeeding**, sudden weight loss or gain, intense exercise, **stress**, endocrine disorders affecting the thyroid, pituitary, or adrenal glands, including Cushing's syndrome and **hyperthyroidism**, and problems with or surgery on the ovaries, including removal of the ovaries, cysts or ovarian tumors.

Amenorrhea in athletes or dancers is frequently associated with two other disorders—osteopenia, or reduced bone mass, and **eating disorders**. This combination is sometimes called the female athlete triad. Osteopenia is of concern because it can lead to premature **osteoporosis**.

Dysmenorrhea

Primary dysmenorrhea is related to the production of prostaglandins, natural chemicals the body makes that cause an inflammatory reaction. They also cause the muscles of the uterus to contract, thus helping the uterus shed the lining built up during the first part of a woman's cycle. Women with severe menstrual pain have higher levels of prostaglandin in their menstrual blood than women who do not have such pain. In some women, prostaglandins can cause some of the smooth muscles in the gastrointestinal tract to contract, resulting in the nausea, vomiting, and diarrhea some women experience. Prostaglandins also cause the arteries and veins to expand, so that blood collects in them rather than flowing freely through them, causing pain and heaviness. Yet another reason for severe cramps, particularly in women who have not yet had a baby, is that the flow of the blood and clots through the tiny cervical opening is painful. After a woman has a baby, however, the cervix opening is larger.

Secondary dysmenorrhea is more serious and is related to some underlying cause. The pain may feel like regular menstrual cramps, but may last longer than normal and occur throughout the month. It may be stronger on one side of the body than the other. Possible causes include:

- a tipped uterus
- endometriosis, a condition in which the same type of tissue found in the lining of the uterus occurs outside the uterus, usually elsewhere in the pelvic cavity
- adenomyosis, a condition in which the endometrial lining grows into the muscle of the uterus
- fibroids
- pelvic inflammatory disease (PID)
- an IUD
- a uterine, ovarian, bowel, or bladder tumor
- uterine polyps
- inflammatory bowel disease
- scarring or adhesions from earlier surgery

Menorrhagia

Heavy bleeding during menstruation is usually related to a hormonal imbalance, although other causes include fibroids, cervical or endometrial polyps, the autoimmune disease lupus, **pelvic inflammatory disease** (PID), blood platelet disorder, a hereditary blood factor deficiency, or, possibly, some reproductive cancers. Thus, menorrhagia is actually a symptom of an underlying condition rather than a disease itself. It may also be related to the use of an IUD.

Women with menorrhagia experience not only significant inconvenience, but may feel very tired due to the loss of iron-rich blood. It is usually diagnosed when a woman soaks through a tampon or pad every hour for several hours or has a period lasting more than seven days. Clots are not related to menorrhagia, although women with heavy cycles may pass clots. They are typically a normal part of menstruation, more common when a woman has been sitting or in a stationary position for a while.

Diagnosis

Women should seek care from a gynecologist, family practitioner, or internist for menstrual irregularities. Depending on the problem, various tests and procedures will be performed, but the one common to any menstrual problem is a **pelvic exam**. This should

KEY TERMS

Adenomyosis—Uterine thickening caused when endometrial tissue, which normally lines the uterus, extends outward into the fibrous and muscular tissue of the uterus.

Cervical polyps—Growths originating from the surface of the cervix or endocervical canal. These small, fragile growths hang from a stalk and protrude through the cervical opening (the os).

Cushing's syndrome—A group of conditions caused by increased production of cortisol hormones or by the administration of glucocorticoid hormones (cortisone-like hormones).

Endometriosis—A condition in which the tissue that normally lines the uterus (endometrium) grows in other areas of the body, causing pain, irregular bleeding, and frequently, infertility.

Fibroids—Benign tumors of muscle and connective tissue that develop within or are attached to the uterine wall.

Hyperthyroidism—An imbalance in metabolism that occurs from overproduction of thyroid hormone.

Inflammatory bowel disease—A chronic inflammatory disease that can affect any part of the gastrointestinal tract but most commonly affects the ileum.

Lupus (systemic lupus erythematosus or SLE)—A chronic inflammatory autoimmune disorder that may affect many organ systems, including the skin, joints, and internal organs.

Menarche—The first menstrual period or the establishment of the menstrual function.

Osteopenia—Reduction in bone mass, usually caused by a lowered rate of formation of new bone that is insufficient to keep up with the rate of bone destruction. Osteopenia often occurs together with amenorrhea and eating disorders in female athletes. It can lead to premature osteoporosis if left untreated.

Pelvic inflammatory disease (PID)—A general term referring to infection involving the lining of the uterus, the Fallopian tubes, or the ovaries.

Turner's syndrome—A disorder in women caused by an inherited chromosomal defect. This disorder inhibits sexual development and causes infertility. A symptom is absence of menstruation.

be scheduled when women are not menstruating, simply for convenience.

Examination

Male doctors typically have a female nurse or assistant in the room. The examination begins by checking the external genitalia for any sores or irregularities. Then the doctor inserts a speculum (a metal duckbill-shaped device that holds open the vagina) into the vagina and peers throughout the opening to evaluate the health of the cervix (opening of the uterus), and inside the vagina, looking for growths or any other abnormalities.

The doctor also manually examines the woman, inserting two fingers into the vagina while pressing on the abdomen, again feeling for any lumps or other abnormalities, checking the size and shape of the reproductive organs, and watching for any signs of infection, such as tenderness or pain. The exam is typically covered by insurance and takes about ten minutes.

Tests

Several different tests may be done for menstrual irregularities. Blood, stool, and urine tests may be conducted to check for levels of various hormones, blood cells, and other chemicals. In the absence of menses, a pregnancy test can be done to test for the presence of certain hormones that indicate a pregnancy has occurred.

An **ultrasound**, typically performed by a trained ultrasound technologist, involves using sound waves to get an image of the reproductive system. It is used to look for fibroids and other ovarian abnormalities that may cause heavy bleeding or cramps. Typically, the technologist smears a jelly over the woman's stomach, then places a probe on her stomach and watches the images appear on a computer screen. It is painless. Women may be asked not to urinate for several hours prior to the test, as a full bladder makes it easier to see the other internal organs. The test takes about 20 minutes.

An **endometrial biopsy** is used to check the health of uterine tissue in women who have unusually heavy bleeding. This test should be performed by the physician. Women should take a pain reliever such as ibuprofen or naproxen prior to the procedure, as there may be some cramping. The woman lies back on the table with her feet in stirrups, and the doctor inserts a

WWW.BOOKBAZ.IR

speculum, then opens the cervix slightly with an instrument called a tenaculum. Then the doctor slides a small, hollow catheter into the uterus and sucks out a small piece of tissue from the uterine lining. The tissue is examined for any abnormalities in a laboratory. The test takes about 30 minutes and is typically covered by insurance. Some bleeding may result afterward.

Procedures

Dilatation and curettage (D&C) is a very common minor surgical procedure in which the cervix is opened and the lining of the uterus is scraped. This procedure is performed for the purpose of diagnosis as well as treatment for problems such as cervical polyps or **endometriosis**. It is also performed after a **miscarriage** or abortion.

Laparascopy and **hysteroscopy** are surgical procedures in which a small camera is inserted into the woman to view the inside of the pelvis, abdomen, or uterus.

Treatment

Amenorrhea

For primary amenorrhea with no underlying problem, no treatment is necessary, and a wait-and-see approach is often adopted. If women have genetic or hormonal abnormalities, amenorrhea is often treated with **oral contraceptives** that contain combinations of estrogen and progestin. Side effects include bloating, weight gain, and **acne**, although some birth control pills actually improve acne. Progestins, or synthetic progesterone, are also used alone to start a woman's period. They include medroxyprogesterone (Provera, Amen, Depo-Provera), norethindrone acetate (Aygestin, Norlutate), and norgestrel (Ovrel). If the amenorrhea is due to a physical problem, such as a closed vagina, surgery may be required.

With secondary amenorrhea, treatment depends on the cause. Hormonal imbalances are treated with supplemental hormones. Tumors or cysts may require surgery. **Obesity** may require a diet and exercise regimen, while amenorrhea resulting from too much dieting or exercise necessitates lifestyle changes.

Dysmenorrhea

Primary dysmenorrhea is typically treated with nonsteroidal anti-inflammatory medications like ibuprofen and naproxen, which studies show help 64–100% of women. Birth control pills relieve pain and symptoms in about 90% of women by suppressing ovulation and reducing the amount of menstrual blood. It may take up to three cycles before a woman feels relief. Heat from a heating pad or hot bath, can also help relieve pain.

Treatment for secondary dysmenorrhea depends on the underlying cause of the condition.

Menorrhagia

If there are no other problems, and the bleeding is due to hormonal imbalances, birth control pills are often prescribed to bring the bleeding under control and regulate menstruation. Such medications as ibuprofen and naproxen can also help reduce the bleeding and any cramping associated with it. In severe cases, doctors may recommend removing the uterus during a **hysterectomy**, or performing some form of endometrial ablation, which removes the lining of the uterus. These procedures are typically only offered to women who have completed their families. A recent British study reported that many women prefer endometrial ablation to hysterectomy because it is less invasive and safer. In 2009, the FDA approved the intrauterine hormonal device, Mirena, for use in women experiencing heavy bleeding.

Premenstrual dysphoric disorder (PMDD)

Medications that have been reported to be effective in treating PMDD include the tricyclic antidepressants and the **selective serotonin reuptake inhibitors** (SSRIs). Effective treatments other than medications include cognitive behavioral therapy (CBT), aerobic exercise, and dietary supplements containing **calcium**, magnesium, and vitamin B_6.

Alternatives

Amenorrhea

There are several herbal remedies that can bring on menstruation, including: black cohosh, cramp bark, chasteberry, celery, turmeric, and marsh mallow. Numerous relaxation techniques, such as **meditation**, deep breathing, and **yoga** can help reduce stress and its effects on menstruation.

Dysmenorrhea

Alternative treatments used to help relieve menstrual pain include:

- Transcutaneous electrical nerve stimulation (TENS). Several studies found relieved pain in 42–60% of participants, working faster than naproxen in one study.
- Acupuncture: One study of 43 patients followed for a year found that 90% of those who had acupuncture

once a week for three menstrual cycles had less pain, and 43% used less pain medication.

- Omega-3 fatty acids: Often sold as fish oil supplements, they are a known anti-inflammatory, working against the effects of prostaglandins. Studies found that women with low amounts of omega-3 fatty acids in their diets were more likely to have menstrual cramps; those who took supplements had less pain.
- Vitamin B_1: One large study found that symptoms disappeared in 87% of women who took 100 mg a day for 90 days.
- Magnesium supplements: One study of 30 women who took 4.5 mg of oral magnesium three times daily for part of the month decreased their symptoms up to 84%.

Menorrhagia

Herbs used to treat menorrhagia include yarrow, nettles, and shepherd's purse, as well as agrimony (particularly used in Chinese medicine), ladies mantle, vervain, and red raspberry, which are thought to strengthen the uterus. Vitex is another herb recommended for a variety of menstrual disorders ranging from menorrhagia to **premenstrual syndrome** (PMS). Women may want to discuss with their doctor about taking an iron supplement to replace the iron lost during the heavy bleeding. Helpful **vitamins** include **vitamin A**, because women with heavy bleeding typically have lower levels of vitamins A, K (aids in clotting), and C and bioflavinoids, which help strengthen veins and capillaries. Zinc may also help.

Prognosis

The prognosis for all menstrual irregularities is good once treatment is initiated.

Prevention

Amenorrhea

Simply following a healthy exercise and nutritional program can help prevent amenorrhea, as can reducing stress and learning relaxation techniques. Avoiding excessive alcohol intake and quitting **smoking** may prevent missed periods.

Dysmenorrhea

Prevention includes taking certain dietary supplements and vitamins. Exercise may also help.

Menorrhagia

There is little women can do to prevent this menstrual irregularity other than discovering the root cause.

Mental health hold

Definition

A mental health hold, sometimes called a psychiatric hold, is the involuntary detaining and hospitalization for further evaluation of a person in apparent need of mental health care.

Description

A mental health hold can be categorized as urgent or emergent. Emergent causes can include individuals exhibiting abnormal vital signs (e.g., breathing, pulse rate, temperature, blood pressure), threatening or violent behavior, and those who exhibit signs and symptoms of alcohol or illicit drug intoxication. Urgent use of a mental health hold is indicated in individuals showing suicidal thoughts, extreme anxiety, homicidal tendencies, violence, or a danger to self or the public. Specific criteria for initiating the hold vary from state to state. The hold or involuntary confinement can last no more than 72 hours, after which the individual must be released or committed to an inpatient facility.

Purpose

The primary purpose of a mental health hold is to protect the individual and the public from an urgent or emergent condition that could cause danger to the affected person or others, or cause severe disability to the extent whereby the affected person is unable to care for himself or herself.

Preparation

Those individuals categorized as emergent should be prepared for further testing, which can include blood chemistries, urinalysis, and psychological assessment and evaluation. In some cases, the individual may need to be restrained with four-point leather restraints (both arms and both legs) and placed in a quiet room with a sitter. For those with urgent needs, restraint may be initiated and initial management is directed to assess for an underlying medical cause and address psychological needs.

Aftercare

Further assessment, testing, and evaluation is necessary for a definitive diagnosis and to devise an appropriate treatment plan.

Risks

A deficiency in record keeping can lead to legal problems. The criteria and specifications for confinement should be clearly indicated and may vary from state to state. Meticulous clinical examination and documentation is essential for a definitive diagnosis. Persons who are confined due to substance abuse problems may have legal issues.

Because a mental health hold has medicolegal implications, clinicians using this form of patient restraint should perform a comprehensive mental status examination and document the findings. This approach helps to provide clear records establishing the specific presenting problems and symptoms, avoiding future ambiguities.

Mental status examination

Definition

A mental status examination (MSE) is an assessment of a patient's level of cognitive (knowledge-related) ability, appearance, emotional mood, and speech and thought patterns at the time of evaluation. It is one part of a full neurologic (nervous system) examination and includes the examiner's observations about the patient's attitude and cooperativeness as well as the patient's answers to specific questions. The most commonly used test of cognitive functioning per se is the so-called Folstein Mini-Mental Status Examination (MMSE), developed in 1975.

Purpose

The purpose of a mental status examination is to assess the presence and extent of a person's mental impairment. The cognitive functions that are measured during the MSE include the person's sense of time, place, and personal identity; memory; speech; general intellectual level; mathematical ability; insight or judgment; and reasoning or problem-solving ability. Complete MSEs are most commonly given to elderly people and to other patients being evaluated for **dementia** (including AIDS-related dementia). Dementia is an overall decline in a person's intellectual function—including difficulties with language, simple calculations, planning or decision-making, and motor (muscular movement) skills as well as loss of memory. The MSE is an important part of the differential diagnosis of dementia and other psychiatric symptoms or disorders. The MSE results may suggest specific areas for further testing or specific types of required tests. A mental status examination can also be given repeatedly to monitor or document changes in a patient's condition.

Precautions

The MSE cannot be given to a patient who cannot pay attention to the examiner, for example as a result of being in a **coma** or unconscious; or is completely unable to speak (aphasic); or is not fluent in the language of the examiner.

Description

The MMSE of Folstein evaluates five areas of mental status, namely, orientation, registration, attention and calculation, recall, and language. A complete MSE is more comprehensive and evaluates the following ten areas of functioning:

- Appearance. The examiner notes the person's age, race, sex, civil status, and overall appearance. These features are significant because poor personal hygiene or grooming may reflect a loss of interest in self-care or physical inability to bathe or dress oneself.
- Movement and behavior. The examiner observes the person's gait (manner of walking), posture, coordination, eye contact, facial expressions, and similar behaviors. Problems with walking or coordination may reflect a disorder of the central nervous system.
- Affect. Affect refers to a person's outwardly observable emotional reactions. It may include either a lack of emotional response to an event or an overreaction.
- Mood. Mood refers to the underlying emotional "atmosphere" or tone of the person's answers.
- Speech. The examiner evaluates the volume of the person's voice, the rate or speed of speech, the length of answers to questions, the appropriateness and clarity of the answers, and similar characteristics.
- Thought content. The examiner assesses what the patient is saying for indications of hallucinations, delusions, obsessions, symptoms of dissociation, or thoughts of suicide. Dissociation refers to the splitting-off of certain memories or mental processes from conscious awareness. Dissociative symptoms include feelings of unreality, depersonalization, and confusion about one's identity.
- Thought process. Thought process refers to the logical connections between thoughts and their relevance to the main thread of conversation. Irrelevant detail, repeated words and phrases, interrupted thinking (thought blocking), and loose, illogical connections between thoughts, may be signs of a thought disorder.
- Cognition. Cognition refers to the act or condition of knowing. The evaluation assesses the person's orientation (ability to locate himself or herself) with regard to time, place, and personal identity; long- and short-term memory; ability to perform simple arithmetic (counting backward by threes or sevens); general intellectual level or fund of knowledge (identifying the last five presidents, or similar questions); ability to think abstractly (explaining a proverb); ability to name specified objects and read or write complete sentences; ability to understand and perform a task (showing the examiner how to comb one's hair or throw a ball); ability to draw a simple map or copy a design or geometrical figure; ability to distinguish between right and left.
- Judgment. The examiner asks the person what he or she would do about a commonsense problem, such as running out of a prescription medication.

WWW.BOOKBAZ.IR

- Insight. Insight refers to a person's ability to recognize a problem and understand its nature and severity.

The length of time required for a mental status examination depends on the patient's condition. It may take as little as five minutes to examine a healthy person. Patients with speech problems or intellectual impairments, dementia, or other organic brain disorders may require fifteen or twenty minutes. The examiner may choose to spend more time on certain portions of the MSE and less time on others, depending on the patient's condition and answers.

Preparation

Preparation for a mental status examination includes a careful medical and psychiatric history of the patient. The history helps the examiner to interpret the patient's appearance and answers with greater accuracy, because some physical illnesses may produce psychiatric symptoms or require medications that influence the patient's mood or attentiveness. The psychiatric history should include a family history as well as the patient's personal history of development, behavior patterns, and previous treatment for mental disorders (if any). Symptoms of dissociation, for example, often point to a history of childhood **abuse**, rape, or other severe emotional traumas in adult life. The examiner should also include information about the patient's occupation, level of education, marital status, and right- or left-handedness. Information about occupation and education helps in evaluating the patient's use of language, extent of **memory loss**, reasoning ability, and similar functions. Handedness is important in determining which half of the patient's brain is involved in writing, picking up a pencil, or other similar tasks that he or she may be asked to perform during the examination.

Aftercare

Depending on the examiner's specific observations, the patient may be given additional tests for follow-up. These tests might include blood or urine samples to test for drug or alcohol abuse, anemia, diabetes, disorders of the liver or kidneys, vitamin or thyroid deficiencies, medication side effects, or **syphilis** and **AIDS**. Brain imaging (CT, MRI, or PET scans) may be used to look for signs of seizures, strokes, head **trauma**, brain tumors, or other evidence of damage to specific parts of the brain. A spinal tap may be performed if the doctor thinks the patient may have an infection of the central nervous system.

KEY TERMS

Aphasia—The loss of the ability to speak, or to understand written or spoken language. A person who cannot speak or understand language is said to be aphasic.

Cognition—The act or process of knowing or perceiving.

Coma—A state of prolonged unconsciousness in which a person cannot respond to spoken commands or mildly painful physical stimuli.

Delusion—A belief that is resistant to reason or contrary to actual fact. Common delusions include delusions of persecution, delusions about one's importance (sometimes called delusions of grandeur), or delusions of being controlled by others.

Dementia—A decline in a person's level of intellectual functioning. Dementia includes memory loss as well as difficulties with language, simple calculations, planning or decision-making, and motor (muscular movement) skills.

Dissociation—The splitting off of certain mental processes from conscious awareness. Specific symptoms of dissociation include feelings of unreality, depersonalization, and confusion about one's identity.

Hallucination—A sensory experience, usually involving either sight or hearing, of something that does not exist outside the mind.

Illusion—A false visual perception of an object that others perceive correctly. A common example is the number of sightings of "UFOs" that turn out to be airplanes or weather balloons.

Obsession—Domination of thoughts or feelings by a persistent idea, desire, or image.

Organic brain disorder—Impaired brain function due to damage or deterioration of brain tissue.

Results

Normal results for a mental status examination depend to some extent on the patient's history, level of education, and recent life events. For example, a depressed mood is appropriate in the context of a recent death or other sad event in the patient's family but inappropriate in the context of a recent pay raise. Speech patterns are often influenced by racial or ethnic background as well as by occupation or schooling. In

general, however, the absence of obvious **delusions**, **hallucinations**, or thought disorders together with the presence of insight, good judgment, and socially appropriate appearance and behavior are considered normal results. A normal numerical score for the MMSE is between 28 and 30.

Abnormal results

Abnormal results for a mental status examination include:

- Any evidence of organic brain damage
- Evidence of thought disorders
- A mood or affect that is clearly inappropriate to its context
- Thoughts of suicide
- Disturbed speech patterns
- Dissociative symptoms
- Delusions or hallucinations

A score below 27 on the MMSE usually indicates an organic brain disorder.

Mercury poisoning

Definition

Mercury **poisoning** is exposure to harmful amounts of the toxic element, usually by breathing mercury vapors or ingesting compounds containing mercury. Mercury poisoning can permanently damage the nervous system and immune system, as well as the brain, lungs, kidneys, heart, and liver. High-level exposure can be fatal. Developing fetuses are particularly sensitive to mercury poisoning.

Demographics

The prevalence of mercury poisoning in American children is hotly debated, but is generally considered to be rare. Fish and shellfish contaminated with methylmercury are the major sources of mercury poisoning in the United States and around the world. A 2009 study by the U.S. Centers for Disease Control and Prevention (CDC) on the exposure of children to elemental mercury found that the largest releases exposing the most children were caused by children stealing mercury from a school or industrial site. The vast majority of elemental exposures:

- were minimal or nontoxic
- occurred in homes or schools
- involved broken thermometers

Description

Mercury (Hg) is a naturally occurring element in air, water, and soil. There are three forms of mercury that pose different potential health hazards:

- Elemental or metallic mercury, also called quicksilver, is a shiny, silvery metal that is a liquid at room temperature, but is easily vaporized to a colorless, odorless gas that can be inhaled. Elemental mercury is released into the air by natural processes such as volcanic activity and by various industrial processes, especially coal–burning power plants. It is extremely poisonous and 79–80% of inhaled mercury vapor is absorbed by the lungs. In the past, mercury vapors poisoned hat makers—hence the Mad Hatter of *Alice in Wonderland*. Elemental mercury is used in thermometers, compact fluorescent light bulbs (CFLs), electrical switches, and older-type dental fillings.
- Inorganic mercury compounds include mercuric oxide (HgO) and mercuric salts, such as mercuric chloride ($HgCl_2$). These compounds are usually white powders or crystals. Inorganic mercury is used in many industries and can be found in some skin ointments and creams, disinfectants, fungicides, folk medicines, red cinnabar pigment, and button batteries that power small electronics.
- Organic mercury compounds are carbon–containing substances, such as methylmercury, ethylmercury, and phenylmercury. Bacteria in soil and water convert inorganic mercury in the environment into methylmercury, which accumulates in fish. Larger and older fish generally have the highest levels of methylmercury. In some parts of the world, organic mercury is used as an antifungal agent in seed grain fed to animals. It is also found in older antiseptics and in some medical preservatives, including trace amounts of thimerosal in some childhood vaccines.

Because the body cannot easily rid itself of mercury, repeated exposure result in its build up in tissues. Elemental mercury vapor and methylmercury are the most dangerous forms because they readily reach the brain. Most humans have trace amounts of methylmercury in their bodies. Methylmercury crosses the placenta to the developing fetus, whose red blood cells can have mercury concentrations that are 30% higher than those of the mother. It also passes to the newborn child through breast milk. Fetuses, infants, and young children are significantly more sensitive to the effects of mercury than adults. During the 1950s, large amounts of organic mercury were dumped in Japan's Minamata Bay, killing some 1,000 people and causing severe nervous system damage in unborn children. Thus mercury poisoning is sometimes called fetal Minamata Bay disease. Mercury poisonings have also occurred from eating meat from animals fed contaminated grain.

Risk factors

The major risk factor for mercury poisoning in children is the consumption of large amounts of contaminated fish and shellfish. Children who play with found or spilled mercury are also at risk.

Causes and symptoms

The most common cause of mercury poisoning is eating fish and shellfish contaminated with high levels of methylmercury. Less common causes of mercury poisoning include:

- inhalation of vapors from spills, breakage of mercury-containing devices, off–gassing from polyurethane flooring containing a mercury catalyst, or mercury accumulation in poorly ventilated buildings
- breathing contaminated air from incinerators or industry
- inadequate remediation of toxic sites
- mercury used in cultural rituals or ceremonies
- mercury tracked home from workplaces
- mercury-based amalgams in dental fillings

- swallowing or inhaling mercury-containing batteries or their components
- direct skin contact with the element or its compounds

The same level of mercury vapor can result in higher mercury concentrations in children than in adults, because children have larger lung surface areas for their body weight. Furthermore, since mercury vapors are more dense than air, there are higher levels closer to the ground where children breathe in the vapors. Although elemental mercury vapor is only slowly absorbed through the skin, it can irritate the skin and eyes and cause **contact dermatitis**. Touching or swallowing elemental liquid mercury is usually not harmful because it rolls off the skin and very little is absorbed by the gastrointestinal tract.

The effects of mercury exposure depend on a variety of factors:

- form of mercury
- dose
- route of exposure—inhaled, ingested, or skin contact
- child's age, with fetuses and very young children being most susceptible
- child's health

Symptoms of elemental mercury poisoning appear within a few hours of exposure to high levels of vapor. Smaller amounts inhaled daily cause symptoms that develop over time. Symptoms can include:

- a metallic taste
- swollen, bleeding gums
- skin rashes
- eye irritation
- respiratory symptoms, especially in children, including severe coughing, shortness of breath, or difficulty breathing
- gastrointestinal symptoms, including nausea, vomiting, and diarrhea
- fever and chills
- high blood pressure or heart rate
- headaches
- neuromuscular symptoms, such as weakness, twitching, tremors, muscle atrophy, and impaired nerve responses
- emotional effects, such as mood swings, irritability, nervousness, or excessive shyness
- insomnia
- disturbed sensations
- cognitive impairment
- with high exposure, kidney impairment, respiratory failure, and death

Unlike elemental mercury, inorganic and organic mercury are absorbed through the intestinal tract, although a swallowed battery may pass harmlessly through a child. Symptoms of inorganic mercury poisoning include:

- skin rashes and dermatitis
- metallic taste
- drooling
- mouth lesions, severe mouth pain, and throat swelling
- severe abdominal pain
- vomiting
- bloody diarrhea
- decreased or absent urination
- severe breathing difficulty
- muscle weakness
- mood swings
- memory loss
- mental disturbances
- shock
- kidney failure
- death

Methylmercury can interfere with the neurological development of fetuses, infants, and children, causing any of the following:

- cerebral palsy
- brain damage and intellectual disabilities (ID)
- language deficits
- attention deficits
- poor coordination
- growth retardation
- blindness
- seizures
- microcephaly (small head)

Symptoms of organic mercury poisoning most often develop over years or decades and include:

- "pins and needles" in the hands and feet and around the mouth
- numbness or pain on the skin
- poor coordination
- tremors
- muscle weakness
- impaired vision or blindness
- impaired speech and hearing
- impaired memory
- seizures and death with high-level exposure

KEY TERMS

Button batteries—Tiny, round batteries containing mercuric chloride that power items such as watches, hearing aids, calculators, cameras, and penlights.

Cerebral palsy—Brain damage before, during, or just after birth that results in lack of muscle coordination and problems with speech.

Chelators—Various compounds that bind to metals such as mercury.

Contact dermatitis—Skin inflammation from contact with an allergen or other irritating substance.

Elemental mercury (Hg)—Metallic mercury; quicksilver; a heavy, silvery, poisonous metallic element that is a liquid at room temperature but vaporizes readily.

Inorganic mercury—Inorganic compounds such as mercuric oxide (HgO) and mercuric chloride ($HgCl_2$).

Mercuric chloride; mercury(II) chloride ($HgCl_2$)—A poisonous crystalline form of inorganic mercury that is used as a disinfectant and fungicide.

Methylmercury—Any of various toxic compounds containing the organic grouping CH_3Hg. These compounds occur as industrial byproducts and pesticide residues, accumulate in fish and other organisms, especially those high on the food chain, and are rapidly absorbed through the human intestine to cause neurological disorders such as Minamata disease.

Organic mercury—Poisonous compounds containing mercury and carbon, such as methylmercury, ethylmercury, and phenylmercury.

Thimerosal—A crystalline organic mercury compound used as an antifungal and antibacterial agent and present in very small amounts in some vaccines.

Diagnosis

Examination

The child's vital signs—including temperature, pulse, breathing rate, and blood pressure—will be monitored. Important diagnostic information includes:

- the type and amount of exposure
- the time and duration of exposure
- the name of the product and its ingredients and strength

Tests

Blood or urine samples can be tested for exposure to elemental and inorganic mercury. Exposure to methylmercury is measured in whole blood or scalp hair. Mercury levels are often expressed as parts per million (ppm). For example, 1 ppm mercury in hair is equal to 1 milligram (mg) per kilogram (kg) of hair. The average mercury level in the hair of unaffected people is 2 ppm. Blood and urine tests may also be used to detect kidney damage from mercury poisoning.

Procedures

- For swallowed inorganic mercury, an endoscope—a flexible instrument with a camera—may be inserted through the throat to look for burns in the esophagus or stomach.
- X rays are taken immediately to locate swallowed batteries and monitor their passing through the gastrointestinal tract.
- X rays may be taken to diagnose lung or kidney damage.

Treatment

Traditional

Although inhaled elemental mercury poisoning can be difficult to treat, possibilities include:

- humidified oxygen or air
- a breathing tube inserted in the lungs
- suctioning mercury out of the lungs

Inorganic mercury poisoning is treated with supportive measures, including possibly intravenous fluids and electrolytes.

- Swallowed mercuric oxide may be treated by gastric lavage, in which a tube is inserted through the mouth to wash out the stomach.
- Swallowed mercuric chloride may be treated by making the person vomit.
- Endoscopy may be used to remove a swallowed battery from the esophagus or stomach.
- An inhaled battery is removed immediately from the larynx with a laryngoscope or from the lungs with a bronchoscope or by surgery.

Treatment for methylmercury poisoning depends on the severity and is similar to treatments for **cerebral palsy**. It may include fluids and electrolytes and **kidney dialysis**.

Drugs

Chelators—drugs that bind mercury and other heavy metals—may be required for weeks or months to remove mercury from the blood and protect the kidneys and brain. Other medications to treat mercury poisoning include:

- activated charcoal to absorb swallowed mercury in the stomach
- drugs to induce vomiting for mercuric chloride poisoning
- laxatives for mercuric oxide or mercuric chloride poisoning
- medications to treat symptoms

Alternatives

There are various alternative types of **chelation therapy**. These include bentonite clay baths and combinations of herbs, amino acids, and other **nutritional supplements**.

Home remedies

Mercury poisoning should be treated by immediately removing the child from the source of exposure, if possible. The U.S. National Poison Control Center should be called for instructions: (800) 222–1222.

Prognosis

- A single low–level exposure to elemental mercury does not usually require treatment and is unlikely to have long–term effects.
- Untreated mercury poisoning can eventually cause pain, muscle weakness, vision loss, paralysis, or death.
- Severe elemental mercury poisoning can cause high-level damage to the lungs, kidneys, and central nervous system, including brain damage. Very large exposures are usually fatal.
- Swallowed batteries usually pass through the gastrointestinal tract without causing serious damage; however the prognosis depends on the type of battery and how quickly the condition is treated.
- Severe inorganic mercury poisoning can cause massive blood and fluid loss, kidney failure, and probable death.
- Mercuric chloride is very toxic and even small swallowed doses can cause kidney failure and death. The prognosis depends on the amount of mercury, the symptoms within the first 10–15 minutes, and how quickly the poisoning is treated. Poisoning that occurs slowly over time may result in permanent brain damage.
- Mercuric oxide poisoning also can lead to organ failure and death.
- Damage from methylmercury is irreversible, although the symptoms do not usually worsen without additional exposure. Chronic brain damage from organic mercury poisoning is hard to treat and some children never recover. Methylmercury poisoning may also increase the risk for heart attacks.
- Both mercuric chloride and methylmercury are considered possible carcinogens.

Prevention

The U.S. Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) recommend that young children and women who are pregnant, may become pregnant, or are nursing take the following steps:

- not eat swordfish, shark, king mackerel, or tilefish, all of which have high mercury levels
- eat up to 12 ounces (340 grams or two average portions) per week of a variety of low–mercury fish and shellfish, such as shrimp, canned light tuna, salmon, pollock, catfish, fish sticks, or fast-food fish
- eat no more than six ounces (170 grams) per week of albacore ("white") tuna steak, which has higher levels of mercury
- check local advisories for fish caught by family and friends in local waters
- eat no more than six ounces (170 grams) per week of noncommercially caught fish from local waters if no advisories are available, and eat no other fish during the week
- feed young children smaller portions of fish

Other preventions for mercury poisoning include:

- teaching children never to touch mercury or any shiny, silver liquid
- carefully handling and properly disposing of mercury-containing products such as thermometers and fluorescent light bulbs
- following established procedures for mercury spills
- never vacuuming up spilled mercury, since this causes vaporization
- keeping children and pregnant women away from areas where liquid mercury is used
- contacting local health departments for large mercury spills

Mesothelioma

Definition

Mesothelioma, also called malignant mesothelioma, is an uncommon disease that causes cancer cells to form within the lining of the chest, abdomen, or around the heart. Its primary cause is believed to be exposure to asbestos. Malignant mesothelioma is also known as asbestos cancer or simply "meso."

Demographics

Mesothelioma remains relatively uncommon in the United States, with approximately 2,500–3,000 new cases reported annually. The incidence rates are much higher in Western Europe (over 5,000 cases reported annually). These numbers are expected to climb over the next 20 years because symptoms do not appear until 30–50 years after asbestos exposure. Older males (median age 60 at diagnosis) are three to five times more likely to develop mesothelioma than females. This is most like because males predominance in those professions with an increased risk of asbestos exposure.

Description

Mesothelioma causes cancerous cells to develop in the body's mesothelium, where they can spread to and damage vital organs and tissue. These malignant cells can also metastasize (spread) to other sites in the body. Mesothelioma is very difficult to diagnose and responds poorly to most treatment modalities, resulting in a poor prognosis.

The disease derives its name from the mesothelium, a sac-like membrane that protects most of the body's internal organs. The mesothelium is divided into two distinct protective layers of cells: the visceral layer directly surrounding the organ and the parietal

layer, a sac around the body cavity. By releasing a lubricating fluid, the mesothelium allows the organs to move more freely within the body cavity. (e.g., in the contraction and expansion of the lungs). The mesothelium also is referred to according to where it is located in the body: pleura (chest), peritoneum (abdomen), and pericardium (heart).

Over two-thirds of all mesothelioma cases begin in the pleura region. Pleural mesothelioma spreads through the chest cavity, occasionally developing in the lungs as well. The disease most commonly causes an excess build-up of fluid inside the chest cavity (**pleural effusion**). This excess fluid increases pressure on the lungs and restricts breathing. In addition, malignant cells can cause the pleural lining to thicken and restrict the breathing space even further.

Peritoneal mesothelioma is the second most common form of the disease, accounting for less than 30% of all cases. Malignant cells form in the peritoneum, affecting the abdomen, bowel, liver, and spleen. Similar to pleural mesothelioma, the peritoneal mesothelioma causes a build up of excess fluid in the abdominal cavity. Normal functions such as digestion can be hindered by the obstruction of organ movement.

Very rare forms of mesothelioma occur in the pericardium, as well as the mesothelium of the male and female reproductive organs. Cystic mesothelioma of the peritoneum, another rare form of the disease, occurs predominantly in women and is more benign in nature.

Malignant mesothelioma takes the form of one of three cell-types: epithelioid (50% to 70% of cases), sarcomatous (7% to 20% of cases), and biphasic/mixed (20% to 35% of cases). Of these cell-types, epithelioid mesothelioma carries the most favorable prognosis, followed by biphasic, and finally sarcomatous (very aggressive).

Causes and symptoms

Causes

Approximately 80% of all mesothelioma patients have a history of asbestos exposure. The majority of these patients were employed in an industry that involved the use of asbestos in some fashion. In addition to occupational exposure, household exposure of family members is not uncommon. An exposed individual can carry the asbestos particles on their clothing, skin, and in their hair when they return home, resulting in paraoccupational exposure. Even brief exposure to asbestos, as little as one to two months, can result in long-term consequences. Although the dangers of asbestos have been known for decades, the long latency period of mesothelioma (30–40 years) means that majority of patients were exposed as far back as the 1950s. Estimates suggest that up to eight million Americans have already been exposed. Workers who, in particular, show a higher incidence of asbestos exposure include:

- insulators (asbestos workers)
- boilermakers
- shipfitters
- steel workers
- maintenance workers
- plumbers
- brake mechanics

Exposure to asbestos most often causes the lose of one copy of chromosome 22. Other changes also appear in tumor suppressor genes. These genes regulate the growth and division of cells. In cancer, the regulatory mechanism malfunctions and cells grow wildly and form tumors.

Symptoms

Mesothelioma is very aggressive once it takes hold. However, its initial symptoms are generally non-specific in nature and/or mimic other conditions, such as persistent **pneumonia** or gastronomical disorders. Some patients will exhibit no symptoms at all. As such, proper evaluation and diagnosis are commonly delayed.

Patients with pleural mesothelioma most commonly exhibit signs of dyspnea, pleural effusions, and/or chest **pain**. The majority of pleural effusion symptoms will appear in the right lung (60% of the time). Patients also may have persistent **cough**, weight loss, weakness, **fever**, and difficulty swallowing (dysphagia).

Patients with peritoneal mesothelioma most commonly show signs of pain and/or swelling in the abdomen from fluid retention or tumor growth. Weight loss, nausea, bowel obstruction, anemia, fever, and swelling in the legs and/or feet are also known symptoms.

Diagnosis

Examination

Only a physician can properly diagnose mesothelioma. A review of the patient's medical history, including any past exposure to asbestos, should be conducted for any patient displaying dyspnea, chest pain, fluid build-up, or pain and/or swelling in the abdomen. This review may be followed with a complete **physical examination** that should involve the use

WWW.BOOKBAZ.IR

of imaging techniques. X rays, computed tomography (CT) scans, and magnetic resonance (MRI) scans of the chest and/or abdomen, as well as lung function tests, provide the doctor with critical diagnostic information. Although **positron emission tomography** scans are expensive and may not be covered under most insurance, this diagnostic tool has proven very useful in determining tumor sites and staging of the disease.

Procedures

If indicated, the doctor may wish to internally examine the patient's chest and/or abdominal cavity. These diagnostic procedures, known as **thoracoscopy** (chest) and peritoneoscopy (abdomen), usually are conducted in a hospital setting. Both procedures involve a fiber-optic imaging tool being inserted into the patient through an incision. These endoscopic tools provide the doctor with a closer look at the body cavity and any abnormal tissue or fluid build-up found therein. Excess fluid can be suctioned out through a needle or tube in a process known as **thoracentesis** (for the chest) or **paracentesis** (for the abdomen). Additionally, the doctor may perform a biopsy of any abnormal tissue they discover during this time. Pathological examination of abnormal tissue, as well as fluid, remains the only effective method of confirming the diagnosis of mesothelioma. Biopsy will also assist the doctor in properly staging the disease's progression.

Cancer staging

Once a confirmation of malignant mesothelioma has been established, the doctor will conduct further tests to determine the extent to which the primary disease has spread. This diagnostic process is known as staging. Malignant pleural mesothelioma of can be broken into four stages:

- Localized Malignant Mesothelioma (Stage 1)—Cancer is present in the right or left pleura. May involve the lung, the pericardium, or diaphragm on that side.
- Advanced Malignant Mesothelioma (Stage 2)—Cancer has spread beyond the right or left pleura to lymph nodes on that side. May involve the lung, the pericardium, or diaphragm on that side.
- Advanced Malignant Mesothelioma (Stage 3)—Cancer has spread into the chest wall, diaphragm, ribs, heart, esophagus, or through the abdominal lining. Nearby lymph nodes may or may not be involved.
- Advanced Malignant Mesothelioma (Stage 4)—Cancer shows evidence of metastasis or spread through the bloodstream to distant organs and/or tissues.

Recurrent malignant mesothelioma may also develop, where the cancer returns in its original location or elsewhere in the body even after treatment.

Treatment

There are three traditional treatment modalities for mesothelioma: surgery, **radiation therapy**, and **chemotherapy**. The location and the stage of the disease, as well as the patient's age and health status, will determine which treatment is most appropriate. Modalities can be combined if indicated. Indeed, the multimodality approach appears to provide the most positive results for treating mesothelioma.

Surgery, the most common treatment, involves the removal of the tumor. In the early stages of mesothelioma, this usually involves removal of a section of the mesothelium and surrounding tissue, but may require removing part of the diaphragm as well. For more advanced stages of the disease, removing the entire lung (a procedure known as **pneumonectomy**) may be the only option.

Radiation therapy, also known as radiotherapy, destroys and shrinks the cancer cells through various types of radiation. Both external (from a machine) and internal (such direct application of as radioisotopes) radiation therapies can be used to treat malignant mesothelioma.

Finally, chemotherapy, a systemic treatment modality, uses **anticancer drugs** to destroy the cancerous cells throughout the body. The majority of drugs used to treat mesothelioma are delivered intravenously. The effectiveness of intracavitary chemotherapy, the process of directly injecting the drugs into the chest or abdominal cavity, is being studied.

Pain and other symptoms caused by fluid build-up around the chest and/or abdomen can be treated by draining excess fluid through a needle or tube. These procedures are known as thoracentesis (chest) and paracentesis (abdomen). Drugs, radiotherapy, and surgery can also relieve or prevent further fluid accumulation.

Physicians are currently studying other treatment modalities, such as immunotherapy, **gene therapy**, and intraoperative **photodynamic therapy**. Individuals with mesothelioma who wish to participate in a clinical trial of an experimental therapy can find a list of clinical trials at http://clinicaltrials.gov. There is no cost to the patient to participate in a clinical trial.

Alternatives

Nutritional issues are common in patients with cancer. The cancer causes some problems with diet

and **nutrition**, while others are related to treatment or medication side effects. Maintaining adequate food intake and balanced nutrition in patients with lung cancer is important. A dietitian who specializes in cancer patients can suggest ways to maintain nutrition during treatment.

Although alternative practitioners may offer remedies for "curing" cancer, there is no known way to rid the body of cancer cells. Turning to unproven alternative remedies may be tempting as health declines, but this is unlikely to be helpful and may interfere with beneficial traditional therapy. Responsible alternative medicine practitioners view cancer as a holistic problem and strive to strengthen and support the physical, mental, and spiritual aspects of patients. Alternative practices that support psychological and spiritual health often prove beneficial to improving the quality of life of the individual with cancer. Techniques to reduce **stress**, such as **acupuncture**, **aromatherapy**, massage, and **reflexology**, can provide addition benefit to the patient's sense of well-being.

Palliative care

Because mesothelioma is an aggressive cancer with a poor prognosis, **palliative care** may be the preferred or only option available to patients. This is particularly true for the advanced stages of the disease. By treating the symptoms rather than the disease itself, the goal of this approach is to improve quality of life rather than to extend life. Palliative care aims to relieve the patient's discomfort caused by dyspnea and pain. Chemotherapy, radiation, and/or surgical treatment as needed to control symptoms, in combination with effective management of pain and respiratory function, should form the basis of proper palliative care of patients with mesothelioma.

Prognosis

The stage, location, and cell-type is involved, as well as the patient's age and health status affect life expectancy. Even with aggressive treatment, the prognosis for mesothelioma patients is poor. Overall survival rate from time of diagnosis is about one year. Pleural mesothelioma offers a median survival time of approximately 16–17 months after initial symptoms. Prognosis for peritoneal mesothelioma is poorer and has a median survival time of only ten months after initial symptoms. The more advanced stages of mesothelioma may offer as little as four or five months of survival time.

The survival time for patients with localized mesothelioma can be extended several months with aggressive therapy, with roughly 20% of patients surviving past the five-year mark. Therapy programs developed at leading cancer centers have extended this survival time even further. In 2010, the five-year survival rate for patients with mesothelioma was 10%. Low as this number is, it represented an improvement over earlier survival times.

KEY TERMS

Asbestos—A naturally occurring mineral, utilized worldwide for its durability and heat resistant qualities. Extremely fibrous in nature, asbestos particles can easily enter the respiratory system and damage sensitive tissue. This damage can result in asbestosis, mesothelioma, and lung cancer.

Dyspnea—A difficulty in breathing or shortness of breath, typically associated with some form of heart or lung disease. Also known as air hunger.

Mesothelium—A membrane/sac that protects the body's major internal organs and allows them freedom of movement (for example, lung contractions). The mesothelium is comprised of several regions, including the abdominal cavity (peritoneum), the chest cavity (pleura), and pericardium (heart).

Palliative—Treatment and care in which the goal is to relieve pain and improve quality of life when a cure is not possible.

Pleural effusion—An abnormal accumulation of fluid in the pleura, a fibrous membrane that lines the inside of the chest cavity and protects the lungs. This accumulation can cause shortness of breath, cough, and chest pain.

Prevention

Avoiding asbestos exposure or taking protective measures if exposure is unavoidable is the best way to prevent mesothelioma. Unfortunately, because of the significant delay between exposure and onset (30–50 years), it is probably too late to prevent the development of mesothelioma for most patients. Not **smoking** may slow the disease's progression and/or prevent other further complications associated with asbestos exposure.

Metabolic acidosis

Definition

Metabolic acidosis is a pH imbalance in which the body has accumulated too much acid and does not have enough bicarbonate to effectively neutralize the effects of the acid.

Description

Metabolic acidosis, as a disruption of the body's acid/base balance, can be a mild symptom brought on by a lack of insulin, a **starvation** diet, or a gastrointestinal disorder like **vomiting** and **diarrhea**. Metabolic acidosis can indicate a more serious problem with a major organ like the liver, heart, or kidneys. It can also be one of the first signs of **drug overdose** or **poisoning**.

Causes and symptoms

Metabolic acidosis occurs when the body has more acid than base in it. Chemists use the term "pH" to describe how acidic or basic a substance is. Based on a scale of 14, a pH of 7.0 is neutral. A pH below 7.0 is an acid; the lower the number, the stronger the acid. A pH above 7.0 is a base; the higher the number, the stronger the base. Blood pH is slightly basic (alkaline), with a normal range of 7.36-7.44.

Acid is a natural by-product of the breakdown of fats and other processes in the body; however, in some conditions, the body does not have enough bicarbonate, an acid neutralizer, to balance the acids produced. This can occur when the body uses fats for energy instead of carbohydrates. Conditions where metabolic acidosis can occur include chronic **alcoholism**, **malnutrition**, and **diabetic ketoacidosis**. Consuming a diet low in carbohydrates and high in fats can also produce metabolic acidosis. The disorder may also be a symptom of another condition like kidney failure, liver failure, or severe diarrhea. The build up of lactic acid in the blood due to such conditions as **heart failure**, **shock**, or cancer, induces metabolic acidosis. Some poisonings and overdoses (**aspirin**, methanol, or ethylene glycol) also produce symptoms of metabolic acidosis.

In mild cases of metabolic acidosis, symptoms include **headache**, lack of energy, and sleepiness. Breathing may become fast and shallow. Nausea, vomiting, diarrhea, **dehydration**, and loss of appetite are also associated with metabolic acidosis. Diabetic patients with symptoms of metabolic acidosis may also have breath that smells fruity. The patient may lose consciousness or become disoriented. Severe cases can produce **coma** and death.

Diagnosis

Metabolic acidosis is suspected based on symptoms, but is usually confirmed by laboratory tests on blood and urine samples. Blood pH below 7.35 confirms the condition. Levels of other blood components, including potassium, glucose, ketones, or lactic acid, may also be above normal ranges. The level of bicarbonate in the blood will be low, usually less than 22 mEq/L. Urine pH may fall below 4.5 in metabolic acidosis.

Treatment

Treatment focuses first on correcting the acid imbalance. Usually, **sodium** bicarbonate and fluids will be injected into the blood through a vein. An intravenous line may be started to administer fluids and allow for the quick injection of other drugs that may be needed. If the patient is diabetic, insulin may be administered. Drugs to regulate blood pressure or heart rate, to prevent seizures, or to control **nausea and vomiting** might be given. Vital signs like pulse, respiration, blood pressure, and body temperature will be monitored. The underlying cause of the metabolic acidosis must also be diagnosed and corrected.

KEY TERMS

Diabetic ketoacidosis—A condition caused by low insulin levels where the amount of sugar and ketones in the blood is high.

pH—A measurement of the acidity or alkalinity of a solution based on the amount of hydrogen ions available. Based on a scale of 14, a pH of 7.0 is neutral. A pH below 7.0 is an acid; the lower the number, the stronger the acid. A pH above 7.0 is a base; the higher the number, the stronger the base. Blood pH is slightly alkaline (basic) with a normal range of 7.36-7.44.

Prognosis

If the metabolic acidosis is recognized and treated promptly, the patient may have no long-term complications, however, the underlying condition that caused the acidosis needs to be corrected or managed. Severe metabolic acidosis that is left untreated will lead to coma and death.

Prevention

Diabetic patients need to routinely test their urine for sugar and acetone, strictly follow their appropriate diet, and take any medications or insulin to prevent metabolic acidosis. Patients receiving **tube feedings** or intravenous feedings must be monitored to prevent dehydration or the accumulation of ketones or lactic acid.

Metabolic alkalosis

Definition

Metabolic alkalosis is a pH imbalance in which the body has accumulated too much of an alkaline substance, such as bicarbonate, and does not have enough acid to effectively neutralize the effects of the alkali.

Description

Metabolic alkalosis, as a disturbance of the body's acid/base balance, can be a mild condition, brought on by **vomiting**, the use of **steroids** or diuretic drugs, or the overuse of **antacids** or **laxatives**. Metabolic alkalosis can also indicate a more serious problem with a major organ such as the kidneys.

Causes and symptoms

Metabolic alkalosis occurs when the body has more base than acid in the system. Chemists use the term "pH" to decribe how acidic or alkaline (also called basic) a substance is. Based on a scale of 14, a pH of 7.0 is neutral. A pH below 7.0 is an acid; the lower the number, the stronger the acid. A pH above 7.0 is alkaline; the higher the number, the stronger the alkali. Blood pH is slightly alkaline, with a normal range of 7.36-7.44. Conditions that lead to a reduced amount of fluid in the body, like vomiting or excessive urination due to use of diuretic drugs, change the balance of fluids and salts. The blood levels of potassium and **sodium** can decrease dramatically, causing symptoms of metabolic alkalosis.

In cases of metabolic alkalosis, slowed breathing may be an initial symptom. The patient may have episodes of apnea (not breathing) that may go on 15 seconds or longer. **Cyanosis**, a bluish or purplish discoloration of the skin, may also develop as a sign of inadequate oxygen intake. Nausea, vomiting, and **diarrhea** may also occur. Other symptoms can include irritability, twitching, confusion, and picking at bedclothes. Rapid heart rate, irregular heart beats, and a drop in blood pressure are also symptoms. Severe cases can lead to convulsions and **coma**.

Diagnosis

Metabolic alkalosis may be suspected based on symptoms, but often may not be noticeable. The condition is usually confirmed by laboratory tests on blood and urine samples. Blood pH above 7.45 confirms the condition. Levels of other blood components, including salts like potassium, sodium, and chloride, fall below normal ranges. The level of bicarbonate in the blood will be high, usually greater than 29 mEq/L. Urine pH may rise to about 7.0 in metabolic alkalosis.

Treatment

Treatment focuses first on correcting the imbalance. An intravenous line may be started to administer

Methadone

Definition

Methadone is a powerful narcotic drug in the same class as heroin. This class is known as the opioids.

Purpose

Methadone, formerly known as dolophine, is a psycho-active drug, meaning that it affects the mind and behavior. It belongs to the class of opioids, drugs that share some of the analgesic properties, and mimic the action of some of the body's naturally occurring chemicals called peptides, such as endorphins and enkephalines.

Methadone is used to relieve chronic **pain** in cancer patients and as a maintenance drug to control withdrawal symptoms in people undergoing treatment for opiate **addiction**.

In opiate addiction treatment, methadone blocks the opioid receptors of the brain that bind opiates such as heroin. The blocking of these receptors leads to two major effects:

- because these chemical receptors remain blocked by methadone for up to 24 hours, even if a person addicted to heroin takes heroin after the administration of methadone, this person is not likely to feel the same effects of the heroin as he or she previously felt;
- because the action of methadone is associated with slower and less intense withdrawal symptoms than those of heroin, the patient can experience milder opiate effects while the addiction is being treated and avoid the unpleasant withdrawal symptoms associated with heroin.

Methadone has also been shown to reduce cravings for heroin while not altering a person's mood.

Precautions

Methadone magnifies the effects of alcohol and other **central nervous system depressants**, such as **antihistamines**, cold medicines, sedatives, tranquilizers, other prescription and over-the-counter (OTC) pain medications, **barbiturates**, seizure medications, **muscle**

KEY TERMS

Analgesic—Any agent that relieves pain.

Central nervous system (CNS) depressant—Any drug that tends to reduce the activity of the central nervous system. The major drug categories included in this classification are: alcohol, anesthetics, anti-anxiety medications, antihistamines, antipsychotics, hypnotics, narcotics, sedatives, and tranquilizers.

Endorphins—Any of several opiate peptides naturally produced in the brain that bind to certain neuron receptors and have the effect of relieving pain.

Enkephalines—Peptide produced by the body that have analgesic properties.

Morphine—The naturally occurring opioid in the opium poppy, *Papaver somniferum*. It is a powerful narcotic analgesic, and its primary clinical use is in the management of moderately severe to severe pain. After heroin, morphine has the greatest potential for addiction of all narcotic analgesics.

Narcotic—Any drug that produces insensibility or stupor and/or generally causes effects similar to those caused by morphine.

Opiate—Any narcotic analgesic derived from a natural source, such as morphine from the opium poppy.

Opioid receptors—Receptors located in the brain and various organs that bind opiates or opioid substances.

Opioids—One of the major classes of semi or fully synthetic psycho-active drugs that includes methadone.

Psychoactive drugs—Any drug that affects the mind or behavior. There are five main classes of psychoactive drugs: opiates and opioids (e.g. heroin and methadone); stimulants (e.g. cocaine, nicotine), depressants (e.g. tranquilizers, antipsychotics, alcohol), hallucinogens (e.g. LSD), and marijuana and hashish.

Receptor—A molecular structure on the surface that selectively binds a specific substance resulting in a specific physiological effect.

relaxants, and certain anesthetics including some dental anesthetics. Alcohol and other central nervous system depressants should not be taken or consumed while methadone is being taken.

Methadone is a powerful narcotic. It can cause some people to feel drowsy, dizzy, or light-headed. People taking methadone should not drive a car or operate machinery.

Intentional or accidental overdose of methadone can lead to unconsciousness, **coma**, or death. The signs of methadone overdose include confusion, difficulty speaking, seizures, severe nervousness or restlessness, severe **dizziness**, severe drowsiness, and/or slow or troubled breathing. These symptoms are increased by alcohol or other central nervous system (CNS) depressants. Anyone who feels that he or she, or someone else, may have overdosed on methadone, or a combination of methadone and other central nervous system depressants, should seek emergency medical attention for that person at once.

Description

A typical adult dosage for methadone is 5–20 mg as an oral solution, 2.5–10 mg as an oral tablet or injection, every four to eight hours as necessary for pain. When used for **detoxification**, methadone is initially given in a dose of 15–100 mg per day as an oral solution. This dose is then decreased until the patient no longer requires the medication. The injection form of methadone is only used for detoxification in patients who are unable to take the medication by mouth.

Preparation

No preparation is generally necessary prior to the intake of methadone as a pain reliever. In cases of maintenance treatments, it is important to be sure that the patient is not currently intoxicated by alcohol, heroin, other opioids, or taking other central nervous system depressants.

Aftercare

Patients receiving methadone should be monitored for adverse reactions to this drug, and/or possible accidental overdose.

Risks

Methadone can interfere with or exacerbate certain medical conditions. For these reasons, it is important that the prescribing physician be informed of any current case, or history of the following:

- alcohol abuse
- brain disease or head injury

WWW.BOOKBAZ.IR

- colitis
- drug dependency, particularly of narcotics
- emotional problems
- emphysema, asthma, or other chronic lung disease
- enlarged prostate
- gallstones or gallbladder disease
- heart disease
- kidney disease
- liver disease
- problems with urination
- seizures
- underactive thyroid

Side effects

The most common side effects of methadone include:

- constipation
- dizziness
- drowsiness
- itching
- nausea
- urine retention
- vomiting

Less common side effects of methadone include:

- abnormally fast or slow heartbeat
- blurred or double vision
- cold, clammy skin
- depression or other mood changes
- dry mouth
- fainting
- hallucinations
- hives
- loss of appetite
- nightmares or unusual dreams
- pinpoint pupils of the eyes
- redness or flushing of the face
- restlessness
- rigid muscles
- ringing or buzzing in the ears
- seizure
- severe drowsiness
- skin reaction at the site of injection
- stomach cramps or pain
- sweating
- trouble sleeping (insomnia)
- yellowing of the skin or whites of the eyes

Normal results

Normal results after the administration of methadone to treat chronic pain is the alleviation of that patient's pain, at least to the point where the pain is bearable.

Normal results of methadone treatment to control heroin addiction, is that the patient reduces heroin intake almost immediately upon starting methadone treatments, followed by complete abstinence, usually within two weeks after starting treatment.

Methamphetamine

Definition

Methamphetamine, or meth, is an addictive central nervous system (CNS) stimulant with limited medical value. The United States Drug Enforcement Administration (DEA) lists methamphetamine as a Schedule II drug, which means it has high abuse potential and must be prescribed by a prescription that cannot be refilled.

Demographics

A 2012 National Survey on Drug Use and Health (NSDUH) reports that about 12 million Americans have tried methamphetamines. The national Monitoring the Future survey of 2014 found that 1% of eighth graders, 1% of 10th graders, and 1.9% of twelfth graders had tried methamphetamine at some time in their lives.

In the United States, methamphetamine use peaks in white men 30–40 years old; however, according the Monitoring the Future survey, the average age of first use in 2012 was 19.7 years. In the United States, methamphetamine use is highest in western

Methamphetamine

Short-term effects:

- Increased alertness
- Rapid and irregular heartbeat
- Rise in blood pressure and body temperature

Long-term effects:

- Anxiety and feelings of confusion
- Dental problems
- Increased risk of contracting diseases such as HIV/AIDS and hepatitis
- Insomnia
- Mood disturbances
- Violent behavior

In 2010, 353,000 Americans aged 12 and older had abused methamphetamine at least once in the past month.

states. Internationally, methamphetamine use is highest in Asia.

Description

Methamphetamine was first synthesized in Japan in 1919 and was used as a drug therapy in **asthma** inhalers in the 1930s. Amphetamines of all kinds were used during World War II by both sides to increase the alertness and prolong wakefulness of soldiers. After the war, the government developed stricter regulations for the manufacture and use of amphetamines, but they remained popular among people who wanted to stay awake for long periods (e.g., students, long-haul truckers) and were commonly used by people who wanted to lose weight. In 1970, more restrictions were put on methamphetamine, so that today it is a Schedule II drug. Despite this, methamphetamine remains a popular drug of abuse.

Methamphetamine is produced illegally in many countries, including the United States, and can be synthesized with readily available materials. The drug's misuse is deemed to be a major societal problem. Methamphetamine is addictive. It goes by the street names of ice, crystal, crystal meth, speed, crank, and glass.

Methamphetamine is similar to other CNS stimulants, such as amphetamine (its parent drug), methylphenidate, and cocaine, in that it stimulates dopamine reward pathways in the brain. Consistent with its stimulant profile, methamphetamine causes increased activity and talkativeness, decreased appetite and **fatigue**, and a general sense of well being. Compared to amphetamine, methamphetamine is more potent and longer lasting, and it has more harmful effects on the brain. In animals, a single high dose of methamphetamine has been shown to damage nerve terminals in the dopamine-containing regions of the brain.

Methamphetamine is a white, odorless, bitter-tasting crystalline powder that easily dissolves in water or alcohol. Misuse occurs in many forms, as methamphetamine can be smoked, snorted, injected, or taken orally. When smoked or injected, methamphetamine enters the brain very rapidly and immediately produces an intense but short-lived rush that many abusers find extremely pleasurable. Snorting or oral ingestion produces euphoria—a feeling of being high—within minutes. As with other abused stimulants, methamphetamine is most often used in a binge-and-crash pattern. A "run" of repeated doses may be continued over the course of days (binge) before stopping (crash). Exhaustion occurs with repeated use of methamphetamine, involving intense fatigue and need for sleep after the stimulation phase.

Approved medical indications for the drug are the sleep disorder **narcolepsy**, **attention deficit hyperactivity disorder (ADHD)**, and extreme **obesity**, but in each case methamphetamine is a second-line drug at best and is used only after other, less harmful drugs have failed.

The prescription drug (brand name Desoxyn) comes in the form of a small white tablet, which is orally ingested. Dosing begins at 5 mg once or twice a day and is increased weekly until the lowest effective dose is attained. Desoxyn should not be taken with other stimulants (including **caffeine** and **decongestants**) or **antidepressant drugs** (especially **monoamine oxidase inhibitors** [MAOs], but also tricyclic antidepressants). Desoxyn should not be taken by patients with **glaucoma**, cardiovascular disease (including **hypertension** and arteriosclerosis), or **hyperthyroidism**.

Causes and symptoms

Short-term effects of methamphetamine relate to its stimulation of the brain and the cardiovascular system. Euphoria and rush, alertness, increased physical activity, and decreased sleep and appetite occur from an increase in available dopamine in the brain.

WWW.BOOKBAZ.IR

KEY TERMS

Central nervous system (CNS)—Part of the nervous system consisting of the brain, cranial nerves and spinal cord. The brain is the center of higher processes, such as thought and emotion and is responsible for the coordination and control of bodily activities and the interpretation of information from the senses. The cranial nerves and spinal cord link the brain to the peripheral nervous system, that is the nerves present in the rest of body.

Dopamine—A neurochemical made in the brain that is involved in many brain activities, including movement and emotion.

Hallucination—A false or distorted perception of objects, sounds, or events that seems real. Hallucinations usually result from drugs or mental disorders.

Psychosis—A serious mental disorder characterized by defective or lost contact with reality often with hallucinations or delusions.

Any or all of these effects can lead to compulsive use of the drug that characterizes **addiction**. In addition, methamphetamine causes rapid heart beat (tachycardia), increased respiration, and increased blood pressure (hypertension), and with very high doses, increased body temperature (hyperthermia) and convulsions can occur.

Chronic use of methamphetamine can result in two hallmark features of addiction: tolerance and dependence. Tolerance to the euphoric effects in particular can prompt abusers to take higher or more frequent doses of the drug. Withdrawal symptoms in chronic users include depression, **anxiety**, fatigue, and an intense craving for the drug. Users who inject methamphetamine risk contracting life-threatening viruses such as HIV and hepatitis through the use of dirty needles.

With repeated use, methamphetamine can cause anxiety, **insomnia**, mood disturbances, confusion, **hallucinations**, **psychosis**, and violent behavior. Psychotic features sometimes emerge, such as **paranoia**, hallucinations, and **delusions**, and can last well after methamphetamine use has stopped. **Stroke** and weight loss are other long-term effects.

Diagnosis

Methamphetamine use may be suspected by the symptoms described above and confirmed with a urine drug screening test

Treatment

For acute intoxication accompanied by psychosis, patients may be calmed by reassurance and a quiet setting, but sometimes **antipsychotic drugs** or sedatives are administered. Substances that prevent absorption from the gastrointestinal tract (e.g., **activated charcoal**) may be used if the drug was taken orally. Additional care is given as needed (e.g., keeping the airways open, treatment of seizures.) Individual with methamphetamine intoxication may be violent, agitated, and a danger to themselves and others.

The most effective treatment for methamphetamine addiction is cognitive-behavioral intervention such as counseling but may also include family education, drug testing, and group support in a twelve-step program. The goal of these modalities is to modify the patient's thinking, expectancies, and behaviors to increase coping skills in the face of life's stressors. Contingent management is a promising behavioral intervention, where incentives are provided in exchange for staying clean and for participating in treatment. Residential programs/therapeutic communities may be helpful, particularly in more severe cases.

Antidepressant drugs such as bupropion (Wellbutrin) can be a useful treatment aid, but as of 2014, there are no FDA-approved medications specifically for the treat stimulant addiction.

Prognosis

Addiction is a complex disorder, and prospects for individual addicts vary widely. Chronic methamphetamine use causes changes in brain and mental function. While some effects are reversible, others are very long lasting and perhaps permanent. Methamphetamine is addictive. Relapses are common, and cravings may continue for a long time after drug use has stopped.

Prevention

Teenagers are a target group for prevention strategies as adolescence and young adulthood are associated with exposure to and an inclination to experiment with drugs. Drug education and prevention programs should begin a early, and parents and teachers should be alert to the possibility of methamphetamine abuse.

Methemoglobinemia

Definition

When excessive hemoglobin in the blood is converted to another chemical that cannot deliver oxygen to tissues, called methemoglobin.

Description

The molecule hemoglobin in the blood is responsible for binding oxygen to give to the body. When hemoglobin is oxidized to methemoglobin its structure changes and it is no longer able to bind oxygen. Hemoglobin is constantly under oxidizing stresses: however, normally less than 1% of a person's hemoglobin is in the methemoglobin state. This is due to the body's systems that reduce methemoglobin back to hemoglobin. Infants have a higher risk of acquiring methemoglobinemia because infant hemoglobin is more prone to be oxidized to methemoglobin.

Causes and symptoms

Methemoglobinemia can either be congenital or acquired.

There are two causes of the congenital form. One cause is a defect in the body's systems to reduce methemoglobin to hemoglobin. The other cause is a mutant form of hemoglobin called hemoglobin M that cannot bind to oxygen. Both of these forms are typically benign.

Acquired methemoglobinemia is caused by an external source, usually a drug or medication. Some of these medications include benzocaine, lidocaine and prilocaine. These medications can inhibit the body's systems of reducing methemoglobin to hemoglobin resulting in methemoglobinemia.

With a methemoglobin level of 3-15% skin can turn to a pale gray or blue (**cyanosis**). With levels above 25% the following symptoms may be present:

- Cyanosis unaffected by oxygen administration
- Blood that is dark or chocolate in color that will not change to red in the presence of oxygen
- Headache
- Weakness
- Confusion
- Chest pain

When methemoglobin levels are above 70% death may result if not treated immediately.

Diagnosis

Diagnosis is based on the symptoms and history. If these are indicative of methemoglobinemia blood tests are performed to confirm the presence and level of methemoglobin.

WWW.BOOKBAZ.IR

KEY TERMS

Cyanosis—When the body does not receive enough oxygen.

Oxidation—When a chemical element or compound loses an electron.

Reduction—When a chemical element or compound gains an electron.

Treatment

For acquired methemoglobinemia the typical treatment is with methylene blue. This is administered with an IV over a five-minute period and results are typically seen within 20 minutes. Methylene blue reduces methemoglobin back to hemoglobin.

Though congenital methemoglobinemia is usually benign, the form due to a defective reducing system can be treated with ascorbic acid (vitamin C) taken daily. The other congenital form due to hemoglobin M has no treatment.

Alternatives

There are not any known alternative treatments for methemoglobinemia. Methylene blue, or a similar treatment, is needed to reduce methemoglobin to hemoglobin.

Prognosis

If found early, acquired methemoglobinemia can be easily treated with no side effects. After treatment with methylene blue the patient can expect a full recovery.

Congenital methemoglobinemia is typically benign and should be observed. If methemoglobinemia symptoms occur the person should be taken to the hospital for treatment.

Prevention

If a person gets methemoglobinemia from a certain medication that medication should be avoided at all costs in the future. For people with congenital methemoglobinemia medications or other substances that are known to oxidize hemoglobin should be avoided.

Microbiology

Definition

Microbiology is the scientific study of microorganisms or microbes, such as bacteria and viruses. The human body has tens of trillions of microorganisms living in and on it. Because they are small, however, they only make up about 1–3 percent of the body's mass. Although some microbes can cause disease, most live in harmony with the human body and many are essential for human health.

Description

Microbiology is the study of microscopic organisms. A microscopic organism is any type of living organism made up of no cells, a single cell, or a cluster of cells. Bacteria, viruses, algae, eukaryotes, protozoa, and fungi are all common microorganisms. Microorganisms influence every aspect of life on Earth. They

are found in the human body, food, animals, water, and on all surfaces. This means that the science of microbiology plays an important role in many different fields including medicine, environmental sciences, engineering, food science, and biotechnology.

Microbiology is a large field that covers many different areas, including medical microbiology, which focuses on diseases in humans. Medical microbiology itself is a broad discipline. It includes:

- immunology, which specializes in the body's immune system and how the body defends itself against bacteria, viruses, and other disease-causing microorganisms
- bacteriology, which studies bacteria
- virology, which places its focus on viruses
- parasitology, which studies of parasites
- epidemiology, which is the study of how diseases spread through populations, or public health

Environmental microbiology is the study of microorganisms and the role they play in the environment around them. This may include the impact of microorganisms on **public health**, such as how the levels of certain bacteria in a lake and their potential effect on swimmers. Environmental microbiologists may study how many microorganisms live in a specific area, how microorganisms interact with larger organisms in the environment, or how microorganisms supply nutrients to other larger organisms. Specific areas within environmental microbiology include geomicrobiologists who relate geologic processes to microorganisms, microbial ecologists, who study how microorganisms interact with the environment around them, and the study of how to use microorganisms to clean up polluted areas.

Microbiologists who work in the food industry are called food microbiologists. They may study how spoiled food can causes illness or develop ways to keep food fresh longer. Food microbiologists might even develop new strains of bacteria to make food taste different or better.

Industrial microbiologists most often work in the industry and use microbiology to develop new and improved products. Many industries employ microbiologists, including agriculture, pharmaceuticals, energy, and waste disposal.

Microbiologists known as microbial geneticists focus on how DNA determines the function of different microorganisms. Often each individual microbial geneticist only focuses on one type of microorganism. With the information they discover, microbial geneticists may become involved with genetic engineering and trying to change how microorganisms or larger organisms look or function.

These are only a few of the areas where microbiologists work. The research that microbiologists do affects every industry and every person around the world. Everyday life continues to develop and improve because of the discoveries microbiologists make.

Origins

Even without being able to see microorganisms, humans long ago understood that something invisible to them could cause disease. As far back as 2800 BCE, types of toilets and sewers were used to control waste to prevent disease. A type of toilet paper was written about in China in 589 AD, and Rome had a water commissioner, whose main work was to keep the drinking water clean. The Romans took clean water so seriously that the punishment for polluting a clean water source was death. Although these societies understood that diseases were communicable, or could be passed from one person to another, they did not realize that some of the same matter they saw on

WWW.BOOKBAZ.IR

rotten food, such as mold, were made up of the microscopic organisms that could make them sick.

Englishman Robert Hooke is believed to be the first person to see microbes under a microscope. He coined the term *cells* after seeing the structure of a plant close up. In his book *Micrographia* published in 1665, Hooke described and illustrated the organisms he viewed using his microscope. It is believed that Hooke's book was the main inspiration behind work done by Anton van Leeuwenhoek. Leeuwenhoek is considered to be one of the world's first microbiologists. Although Leeuwenhoek had no formal education, he made his own lenses and looked at pond water, discovering tiny animals. He wrote to the Royal Society of London about his discovery in 1676. Leeuwenhoek's discovery that there were tiny living creatures all around is one of the foundations of microbiology. Even with this discovery, microbiology did not really develop as an area of medical study for almost 200 years.

A doctor in Vienna, Ignaz Semmelweis, was one of the first doctors who understood just how important hand washing and other sanitary measures are to a hospital. In 1841, Semmelweis noticed that more birthing mothers died of blood infections in the doctor-managed hospital ward than in the ward run by midwives. He also saw a friend die from a blood infection contracted from being cut while doing an **autopsy** on a body with the same infection. These events caused Semmelweis to institute various regulations in order to protect patients and doctors, and to reduce the spread of disease. Semmelweis had doctors wash their hands in disinfectant and change dirty lab coats before working with patients. Although the hospital in Vienna fired Semmelweis for his ideas, he was able to reduce the number of deaths at other hospitals by introducing these measures.

Louis Pasteur is considered the father of modern microbiology. His research disproved the theory of spontaneous generation (the belief that life forms could come out of nowhere and begin to multiply on non-living matter) and founded modern immunology. Pasteur also did work that led to the foundation of pasteurization, which allows food to be kept fresh longer. In addition, through observing chickens, Pasteur realized that chickens became immune to certain bacterial diseases if they first were injected with a weakened version of the bacteria. Those observations helped lead to the germ theory of disease, which states that diseases are caused by microorganisms.

Robert Koch also contributed to the germ theory of disease. He postulated that the steps necessary to prove a disease is caused by a specific microorganism are 1) isolate suspected agents from an infected victim, 2) grow the collected agent in a pure culture, 3) infect a healthy host to show that the collected organism produces a disease, and 4) continue the process by once again isolating and collecting the agent again, but this time from the new victim. These steps still make up the basis of microbiology today.

KEY TERMS

Communicable—A communicable disease is one that is contagious or infectious and can be transmitted between people or species.

Germ theory of disease—The theory that a specific microorganisms cause a specific disease.

Immunology—The branch of medicine that focuses on the body's immune system.

Pasteurization—The process of partially sterilizing food using heat. Pasteurization destroys all harmful microorganisms without changing the food or killing the wanted microorganisms.

The field of microbiology continues to grow and microbiologists are discovering new organisms every year. The Petri dish was invented in 1887, an important tool for growing microorganisms, and viruses were discovered in 1892. Penicillin, which saves thousands of lives each year, was discovered in 1928, and DNA began to be sequenced in 1977. In 1995, the first microbial genomic sequence was published. Since then, many other human pathogens have been sequenced and the information used to develop new drugs and to genetically modify other organisms.

Microbiologists continue to make new discoveries that help doctors improve treatments and other professionals to develop products that improve the people's quality of life.

Purpose

The purpose of microbiology is to understand microorganisms and how they affect humans, animals, plants, and the environment. An especially active area of research within the field of medical microbiology revolves around studies of the **microbiome**, which is the collection of microbes that reside in and on the human body. This is an important not only because of the sheer number of such microbes—among the 37 trillion cells of the human body reside at least 10 times as many microbes—but also because microbes play important roles in both human health and in

human disease. Researchers have only begun to scratch the surface in their understanding of the microbiome, and their ongoing studies will likely have significant ramifications for healthcare in the future.

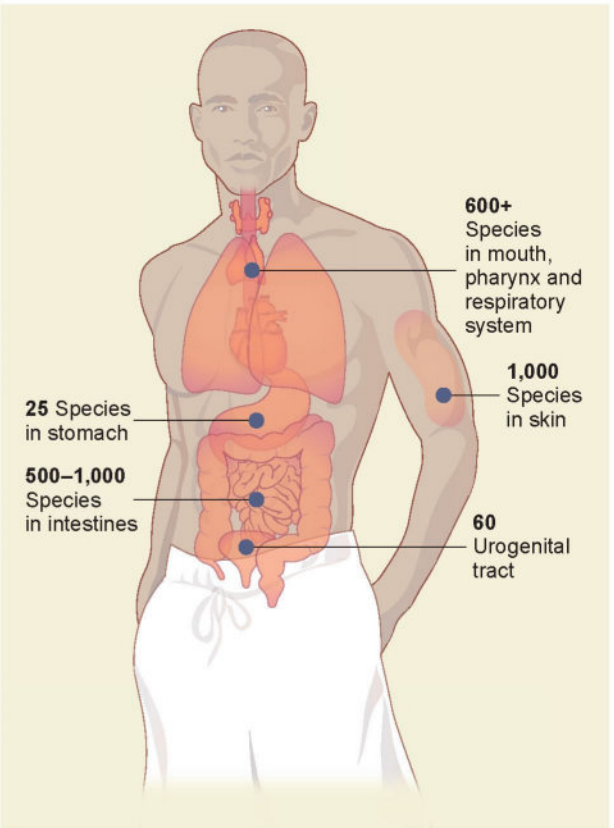
Microbiome

Definition

The term *microbiome* refers to all the microorganisms that exist in a particular environmental niche. The term is derived from the word *biome*, which refers to all of the species that can be found within a specific environment, as applied specifically to the microorganisms that occur within that environment.



(Illustration by Electronic Illustrators Group. © Cengage Learning®.)

Description

American molecular biologist and Nobel Laureate Joshua Ledeberg coined the term *microbiome* in 2001 to describe what he called the "ecological community of commensal, symbiotic, and pathogenic microorganisms that literally share our body space and have been all but ignored as determinants of health and disease." Ledeberg's challenge was an attempt to reverse the condition he was describing, calling on expanded efforts to identify the microorganisms that occur within the human body and to discover their interrelationships with each other and with the body and the impact they have on human health and disease. Since this original challenge, the effort to understand the nature and function of microbiomes has extended far beyond the human body to include virtually all aspects of Earth's atmosphere, lithosphere, and hydrosphere. For example, the Earth Microbiome Project was created in 2011 by a group of

WWW.BOOKBAZ.IR

industrial and research organizations (including Luca Technologies, Illumina, Eppendorf, Pacific Biosciences, Genomic Standards Consortium, and Genome 10K), along with representatives from a number of academic institutions, to study microbial communities from types of soil around the planet. The project hopes to analyze and describe at least 200,000 different soil communities from every part of the planet. Other efforts have been initiated to better understand the microbiomes of seawater and fresh water; the latter, for example, to better understand the interaction between drinking water and human biomes as a means of improving our understanding of human health and disease.

Much research has, however, been directed to Ledeberg's original concern, developing a better understanding of the microbiome that makes up the human body. To some extent, it is strange that this type of research comes so recently, since microorganisms play a very large role in human **physiology** and **biochemistry**. Researchers estimate that the human body contains at least 10 times as many microbial cells as human cells which function, for the most part, in ways that are still not well understood. Any particular region of the body, such as the mouth or the gut, may contain anywhere from three to 10 million microbial genes, compared with the 20,000 or so genes in the human genome itself. This genetic diversity among microbes makes it possible for the microbiome to make an astounding variety of contributions to human health and, in their absence, to account for a number of diseased conditions in the human body. Some experts have described the microbial component of the human body as being so essential as to constitute an organ not unlike the heart, liver, and kidneys. One writer on the topic, for example, has described the human microbiome as "the last human body organ to have been discovered and studied."

The body is home to about 100 trillion bacteria and other microbes, collectively known as the person's microbiome. Naturalists first became aware of them in the 1600s, but it was not until the early 2000s that we have become really familiar with them. Recent research has shown how beneficial our microbes are—breaking down our food, fighting off infections, and nurturing our immune system.

At one time, the task of even identifying the vast array of microorganisms that make up the human microbiome would have been staggering, probably impossible to complete. But a new tool has become available to researchers in the field: DNA analytics. It is now possible to collect and characterize the DNA of most, or all, of the microoganisms in the human microbiome, making it possible for the first time to develop a list of the organisms to be found there. One of the first discoveries made by researchers using this tool is that a significant number of these microorganisms are not bacteria, as one might expect, but archaea, members of one of the three major domains in the three-domain taxonomic system of classifying living organisms (the other two being bacteria and eukaryota). The five main phyla of the archaea domain are Crenarchaeota, Euryarchaeota, Korarchaeota, Nanoarchaeota, and Thaumarchaeota. As of 2014, numerous articles in the scientific literature were devoted to identifying and classifying the microorganisms that make up the human microbiome.

The function of this vast array of microorganisms is not yet well understood. However, some early research has begun to show how critical the organisms are to the maintenance of human health and the variety of ways in which they function in the human body. Some of the earliest of this research came from the field of dentistry, where information as to the way in which microorganisms protect teeth against dental caries (cavities) has become available. One study, for example, found that 1,372 so-called *operation taxonomic units* (OTUs), similar to species, were present in dental plaque, some of which contributed to the preservation of dental enamel (and therefore protection against decay), and some of which contributed to the destruction of enamel (and therefore led to decay). The effect of various types of foods on each of these OTUs can provide information as to ways in which the rate of dental caries is likely to increase or decrease and as to eating habits that can contribute to or detract from good dental health.

Another promising area of research involving the human microbiome is in the relationship between diet and **obesity**. Studies have shown that the ingestion of **antibiotics** can subtly affect the balance of microorganisms in the human gut, reducing the effectiveness with which some of those microorganisms operate. For example, researchers have found in animal studies that the antibiotics used by the agricultural industry to improve food production do not necessarily destroy the microorganisms present in the gut, but they can reduce the effectiveness with which those microorganisms function. For example, they may contribute to the process of metabolism less effectively, meaning that foods that are ingested may not be digested and metabolized as effectively, allowing them to be stored in body tissues and contributing to body weight (which leads to overweight and obesity).

KEY TERMS

Commensalism—A close, long-term relationship between two organisms, in which one organism receives a benefit from the relationship, and the other organism is neither benefited nor harmed by it.

DNA analytics—The use of fragments of DNA to identify and/or classify the organism from which the sample came.

Microorganism—An organism that is too small to be seen by the naked eye, such as a bacterium or a virus.

Pathogen—An organism that causes disease.

Symbiosis—A close, long-term relationship between individuals of two difference species.

A third area of research involves the relationship between the human microbiome and colorectal cancer. In this line of study, researchers have found that the composition of the microbiome present in the vicinity of a colorectal tumor may be slightly different between healthy and diseased tissue. Exactly what this difference means with regard to the development of the tumor is not yet clear, but the new information opens up a line of research that could lead to methods for the prevention and treatment of such tumors.

Microphthalmia and anophthalmia

Definition

Anophthalmia is the complete absence of an eye. Microphthalmia is an eye that is abnormally small.

Description

Anophthalmia is caused by a defect in embryonic development. The total absence of an eye is extremely rare and often a clinical sign associated with a broad range of genetic disorders or, more commonly, a sporadic mutation. Sporadic transmission occurs in the affected individual due to a genetic abnormality. It is not passed on from the parents, but usually due to a combination of environmental and genetic influences. More commonly anophthalmia clinically presents as a small cyst. The defect, which causes anophthalmia, is an absence of the optic vesicle, a structure important for eye development. The genetic abnormality usually occurs during weeks one to three after conception. It is estimated that the incidence of microphthalmia occurs 0.22 times per 1,000 live births. Anophthalmia can occur during adult life but not associated with a genetic cause.

Microphthalmia refers to an abnormally small eye. This clinical sign is often associated with autosomal dominant or recessively transmitted genetic disorders. Most disorders dominantly inherited with microphthalmia are associated with some visual capabilities in infancy and early childhood. Microphthalmia may be isolated (the only presenting sign) or associated with a range of ocular or systemic abnormalities. Isolated cases of microphthalmia may be sporadic or inherited. There is a variable degree of **visual impairment**. Microphthalmia occurs due to autosomal recessive transmission and is part of a syndrome associated with abnormalities in the retina or systemic lesions. Microphthalmia results from a developmental defect after formation of the optic vesicle. The developmental abnormality causes the optic vesicle to fold inwards, resulting in the formation of a cyst. The cyst will progressively swell from birth, and it may be situated along the optic nerve. The cyst may also be situated along other important eye structures.

KEY TERMS

Axial—A straight line passing through a spherical body between its two poles and about which the body may revolve.

Eviscerate—To have removed an organ or the contents of an organ.

Prostheses—A synthetic object that resembles a missing anatomical part.

Retina—A major portion of the eye responsible for reception of visual light rays.

Causes and symptoms

Microphthalmia and anophthalmia can be caused by sporadic or genetic mutations. Anophthalmia is characterized by a total absence of an eye. Anophthalmia in an adult is usually caused by **trauma**, infection, tumor, or advanced eye disease.

Diagnosis

Microscope examination confirms the diagnosis of true anophthalmia. The clinician examines a piece of tissue taken from the eye and notes eviscerated tissue. For microphthalmia the confirmation can be established by eye measurements. Eyes that have an axial length of <21 mm in an adult or <19 mm in a one-year-old child are described as having microphthalmia.

Treatment

Large cysts causing microphthalmia should be aspirated or removed surgically. There is no known cure for anophthalmia or microphthalmia. For anophthalmia a prosthetic eye can be fitted which may involve surgery. Treatment for microphthalmia depends on the complexity of eye involvement.

Prognosis

For anophthalmia, prosthetic eyes should be seen by a specialist two to three times per year to assess fit, mobility, and smoothness. They are usually well tolerated and have good appearance and mobility. The clinical course for microphthalmia depends on the extent of smallness, but usually patients progress favorably without major treatment. Since the smallness is distinctly noticeable, there may be individual cosmetic considerations.

Prevention

There is no known prevention for either, since these clinical signs are commonly associated with genetic inheritance.

Microsurgery

Definition

Microsurgery is surgery that is performed on very small structures, such as blood vessels and nerves, with specialized instruments under a microscope.

Purpose

Microsurgical procedures are performed on parts of the body that are best visualized under a microscope. Examples of such structures are small blood vessels, nerves, and tubes. Microsurgery uses techniques that have been performed by surgeons since the early twentieth century, such as blood vessel repair and organ transplantation, but under conditions that make traditional **vascular surgery** difficult or impossible.

The first microvascular surgery, using a microscope to aid in the repair of blood vessels, was described by Jules Jacobson of the University of Vermont in 1960. The first successful replantation (reattachment of an amputated body part) was reported in 1964 by Harry Bunke. This replantation of a rabbit's ear was significant because blood vessels smaller than 0.04 in. (1 mm)—similar in size to the blood vessels found in a human hand—were successfully attached. Two years later, the successful replantation of a toe to the hand of a monkey was made possible using microsurgical techniques. Soon thereafter, microsurgery began to be used in a number of clinical settings.

Numerous surgical specialties utilize the techniques of microsurgery. Otolaryngologists (ear, nose, and throat doctors) perform microsurgery on the small, delicate structures of the inner ear or the vocal cords. **Cataracts** are removed by ophthalmologists (eye doctors), who also perform corneal transplants and treat eye conditions like **glaucoma**. Urologists can reverse vasectomies (male sterilization), and gynecologists can reverse tubal ligations (female sterilization), giving people new choices about having children. Microsurgical techniques are used by plastic surgeons to reconstruct damaged or disfigured skin, muscles, or other tissues, or to transplant tissues from other parts of the body. A number of specialties can collaborate to treat patients who have lost limbs or other body parts, and under certain circumstances, amputated parts can be reattached, or another body part can be replanted in the place of one lost (for example, a great toe replacing a lost or damaged thumb).

Today, microsurgery can be lifesaving. Neurosurgeons can treat vascular abnormalities found in the brain, and cancerous tumors can be removed.

Description

Equipment

Microsurgical equipment magnifies the operating field, provides instrumentation precise enough to maneuver under high magnification, and allows the surgeon to operate on structures barely visible to the human eye. The most important tools used by the microsurgeon are the microscope, microsurgical instruments, and microsuture materials.

MICROSCOPE. While operating microscopes may differ according to their specific use, certain features are standard. The microscope may be floor- or ceiling-mounted, with a moveable arm that allows the surgeon to manipulate the microscope's position. A view of the surgical site is afforded by a set of lenses and a high-intensity light source. This lighting is enhanced by maintaining a low level of light in the rest of the operating room. Two or more sets of lenses allow a surgeon and an assistant to view the operating field and focus and zoom independently. A video camera allows the rest of the surgical team to view the operating field on a display screen. Features that come with some microscopes include foot- and/or mouth-operated switch controls and motorized zoom and focus.

A magnification of five to forty times (5–40x) is generally required for microsurgery. A lower magnification may be used to identify and expose structures, while a higher magnification is most often used for microsurgical repair. Alternatively, surgical loupes (magnifying lenses mounted on a pair of eyeglasses) may be used for lower magnifications (2–6x).

Robotic-assisted microsurgery improves precision. The operator is seated at a console through which the surgical field is visualized at considerable magnification. Tiny surgical instruments are controlled through the console, allowing very fine movements.

INSTRUMENTS. Microsurgical instruments differ from conventional instruments in a number of ways. They must be capable of delicately manipulating structures barely visible to the naked eye, but with handles large enough to hold comfortably and securely. They must also take into account the tremor of the surgeon's hand, greatly amplified under magnification (although robotic-assisted microsurgery obviates this problem).

Some of the various instruments that are used in microsurgery include:

- forceps
- needle holders (for suturing)
- scissors
- vascular clamps (for controlling bleeding) and clamp applicators
- irrigators (for washing structures in the surgical field)
- vessel dilators (for opening up the cut end of a blood vessel)
- various standard surgical tools

SUTURE MATERIALS. Suturing, or stitching, is done by means of specialized thread and needles. The diameter (gauge) of suture thread ranges in size and depends on the procedure and tissue to be sutured. Conventional suturing usually requires gauges of 2-0 (0.3 mm) to 6-0 (0.07 mm). Conversely, gauges of 9-0 (0.03 mm) to 12-0 (0.001 mm) are generally used for microsurgery. Suture thread may be absorbable (able to be broken down in the body after a definite amount of time) or non-absorbable (retaining its strength indefinitely), natural (made of silk, gut, linen, or other natural material), or synthetic (made of nylon, polyester, wire, or other man-made material). The type of suture thread used depends on the procedure and tissue to be sutured.

The suture needle comes in various sizes (diameters and length) and shapes (straight or curved), and also with different point types (rounded, cutting, or blunt). It comes with suture thread preattached to one

end; this is called the swage. As in the case of suture thread, the type of needle used depends on the procedure and tissue to be sutured; generally, needles with a diameter of less than 0.15 mm are used for microsurgery.

Training

For a surgeon to perform microsurgery in a clinical setting, extensive training and practice are required. A basic knowledge of anatomy and surgical techniques is essential. After a thorough introduction to the operating microscope and other microsurgical equipment, basic techniques are introduced, using small animals as the experimental model. Specifically, surgeons must be taught how to maintain correct posture and to maintain constant visual contact with the microscope during surgery, how to properly hold and use the instruments, how to minimize the amount of hand tremor, and how to perform basic techniques, such as suturing. After becoming proficient at these skills, more advanced techniques can be taught, including procedures regarding how to treat specific conditions.

Extensive and ongoing practice is necessary for a surgeon to maintain adequate proficiency at microsurgical techniques. For this reason, a microsurgical laboratory is made available to surgeons for training and practice. Practice in robotic-assisted microsurgery requires additional training and practice. Some seminars are offered by the companies that produce the equipment utilized in the OR. Ongoing practice is necessary to acquire the hand-eye coordination and comfort level necessary to ensure good technique.

Techniques

Most microsurgical procedures utilize a set of basic techniques that must be mastered by the surgeon. These include blood vessel repair, vein grafting, and nerve repair and grafting.

BLOOD VESSEL REPAIR. Blood vessel or vascular anastomosis is the connection of two cut or separate blood vessels to form a continuous channel. Anastomoses may be end-to-end (between two cut ends of a blood vessel) or end-to-side (a connection of one cut end of a blood vessel to the wall of another vessel).

The first step of creating an anastomosis is to identify and expose the blood vessel by isolating it from surrounding tissues. Each end of the vessel is irrigated (washed) and secured with clamps for the duration of the procedure. A piece of contrast material is placed behind the surgical site so that the tiny vessel can be more easily visualized. The magnification is then increased for the next segment of surgery. The first suture is placed through the full thickness of the vessel wall; the second and third sutures are then placed at 120° from the first. Subsequent sutures are placed evenly in the remaining spaces. Arteries 1 millimeter in diameter generally require between five and eight stitches around the perimeter, and veins of the same size between seven and 10. Once the last suture has been placed, the clamps are released and blood is allowed to flow through the anastomosis. If excessive bleeding occurs between the stitches, the vessel is reclamped and additional sutures are placed.

The procedure for an end-to-side anastomosis is similar, except that an oval-shaped hole is cut in the wall of the recipient vessel. Sutures are first placed at each end of the oval to connect the attaching vessel to the recipient vessel, and then placed evenly to fill in the remaining spaces.

VEIN GRAFTING. Vein grafting is an alternative procedure to end-to-end anastomosis and may be pursued when the cut ends of a blood vessel cannot be attached without tension. Nonessential veins similar in diameter to the recipient blood vessel can be removed from the hand, arm, or foot. If the graft is to be used to reconstruct an artery, its direction is reversed so that the venous valves do not interfere with blood flow. End-to-end anastomosis is then performed on each end of the graft, using the suture techniques described above.

NERVE REPAIR. The process of connecting two cut ends of a nerve is called neurorrhaphy, or nerve anastomosis. Peripheral nerves are composed of bunches of nerve fibers called fascicles that are enclosed by a layer called the perineurium; the epineurium is the outer layer of the nerve that encases the fascicles. Nerve repair may involve suturing of the epineurium only, the perineurium only, or through both layers.

WWW.BOOKBAZ.IR

Many of the techniques used for blood vessel anastomoses are also used for nerves. The cut ends of the nerve are exposed, then isolated from surrounding tissues. The ends are trimmed so that healthy nerve tissue is exposed, and a piece of contrast material placed behind the nerve for better visualization. Each nerve end is examined to determine the pattern of fascicles; the nerve ends are then rotated so that the fascicle patterns align. Sutures may be placed around the circumference of the epineurium; this is called epineurial neurorrhaphy. The perineurium of each cut fascicle end may be stitched with excess epineurium removed (perineurial neurorrhaphy), or both layers may be sutured (epiperineurial neurorrhaphy).

NERVE GRAFTING. If there is a large gap between the cut ends of a nerve, neurorrhaphy cannot be performed without creating tension in the nerve, which can interfere with postsurgical function. A piece of nerve from another part of body may be used to create a nerve graft, which is stitched into place using anastomosis techniques. A disadvantage of nerve grafting is that a loss of function or sensation is experienced from the donor nerve site. A common nerve used for grafting is the sural nerve, which innervates parts of the lower leg.

Preparation

In an emergency situation, such as an **amputation** or crushing injury, a number of steps must be taken immediately to improve the odds that replantation or reconstruction will be successful. An IV line is placed so that fluids and **antibiotics** can be administered. The injured area is x-rayed so that the extent of the injury can be determined, and the amputated body part is wrapped in sterile gauze and placed on ice so that the tissues are preserved. To prevent freezing, the body part must not be packed below the ice. The patient is transported by ambulance or helicopter to the nearest surgical center capable of microsurgical repair.

In other cases, a patient may suffer from a chronic condition or wound, and microsurgery can be scheduled as an elective procedure. Prior to surgery, the patient will be instructed to refrain from tobacco use because it interferes with healing. In addition, the patient will be told not to eat after midnight the day of surgery. It is important that the patient inform the doctor completely about any prior surgeries, medical conditions, or medications taken on a regular basis, including **nonsteroidal anti-inflammatory drugs** (NSAIDs), such as **aspirin**. Patients taking blood thinners, such as warfarin (Coumadin) or heparin, should not adjust their medication themselves, but should speak with their prescribing doctors regarding their upcoming surgery. Patients should never adjust dosage without their doctors' approval. This is especially important for elderly patients, asthmatics, those with **hypertension**, or those who are on ACE inhibitors.

The patient will be placed under general **anesthesia** for the duration of the procedure. The advantages of general anesthesia are that the patient remains unconscious and completely relaxed during the procedure, imperative because of the precise nature and extended duration of the surgery. The patient must be able to tolerate the long surgery and therefore must be relatively stable condition; complex surgeries may take up to 12 hours or more.

Microsurgery makes possible a number of reconstructive procedures that would be more difficult or impossible with conventional surgery. Some of the more frequently performed microsurgical procedures include:

- Replantation. This emergency surgery is performed to reattach an amputated body part such as a finger, arm, or foot. Replantation surgery requires a series of time- and energy-intensive steps to reattach all of the structures while the amputated part is still viable. The cut bone must be shortened slightly so that blood vessels and nerves can be reattached without tension. Anastomoses are created between cut arteries and veins and blood flow is reestablished to the amputated part. Tendons (if present) are then repaired, followed by nerves and soft tissues. Further procedures may be necessary to complete the reconstruction depending on the extent of the injury.
- Transplantation. In some cases an amputated part cannot be reattached, or tissue is deformed because of a congenital defect or an injury. Transplantation may then be an option. The great toe or second toe may be removed from a patient's foot and transplanted to the hand to replace a missing finger. A segment of rib along with its blood supply can be used to reconstruct bones in the face and jaw.
- Free-tissue transfers. Also called free flaps, free-tissue transfers may be used to reconstruct damaged tissues that cannot be treated with skin grafts, closed by traditional methods such as suturing, or allowed to heal without intervention. This includes tissues that have constricted after a burn, injuries in which there is not sufficient skin to properly close the wound, or tissues that have been removed as a result of treatment for cancer. Examples of tissues that may be transferred with microsurgical techniques are skin, muscle, fat, bone, and intestine.

Aftercare

Following surgery, the patient is given intravenous fluids and usually progresses to a liquid diet within 12 to 24 hours, and a regular diet soon thereafter. The patient must be kept warm and adequately hydrated, and the surgical site is elevated when possible to help drain excess fluids. Medications are administered to help manage **pain**. The color, temperature, quality of capillary refill, and tissue turgor (fullness) of the surgical site are closely monitored. Skin should be pink, warm, and have one- to two-second capillary refill. Conversely, tissue that is pale or blue, cool, with no refill or rapid refill may indicate a problem with blood flow.

Certain tests may be recommended to further evaluate the surgical site. These include:

- Doppler ultrasound. This technology uses high-frequency sound waves to evaluate the flow of blood to and from the surgical site.
- Intravenous fluorescein. After a chemical dye called fluorescein is administered to the patient, a specialized machine called a fluorometer is used to determine how much blood is flowing through the surgical site.
- Pulse oximetry. A pulse oximeter measures the amount of oxygen in the blood and tracks the patient's pulse.
- Arteriography. X rays are taken of the surgical site after a contrast dye has been injected into the bloodstream to determine the condition of vascular anastomoses.

When the patient is discharged from the hospital, he or she will receive instructions for aftercare. Exposure to tobacco must be limited for at least six weeks following the surgery, as nicotine interferes with circulation. The patient must remain warm as body temperature also affects circulation. Bed rest may be prescribed for a period of days to weeks after surgery, depending on the procedure. Patients who have had a hand, finger, or multiple fingers replanted must keep the part elevated at heart level to help blood flow and decrease swelling.

Some form of **rehabilitation** is often recommended after microsurgery. This includes a program of individualized exercises used to restore function to a replanted or transplanted body part. In some cases where problems with circulation occur after surgery, leech therapy may be recommended. **Leeches** are worms that attach to the skin and draw blood while also injecting substances into the skin that act as a local anesthetic and an anticoagulant (preventing the formation of **blood clots**). Therapy involves attaching a leech to the replanted part or tissue flap and allowing it to feed for 15 to 30 minutes several times a day until blood flow is established.

Middle East respiratory syndrome

Definition

Middle East respiratory syndrome (MERS) is an emergent respiratory infection caused by a novel coronavirus (CoV) called MERS-CoV. It can cause severe acute respiratory illness. About one-third of confirmed cases have been fatal.

Demographics

MERS was first identified in Saudi Arabia in 2012. Its spread through the Middle East in 2013 raised fears of a new global pandemic. As of October 2014, almost 900 cases had been reported. However, it is assumed that only the most severe cases are diagnosed and recorded and that many more people have probably been infected with the virus.

The disease appears to be circulating widely throughout the Arabian Peninsula, with cases reported from

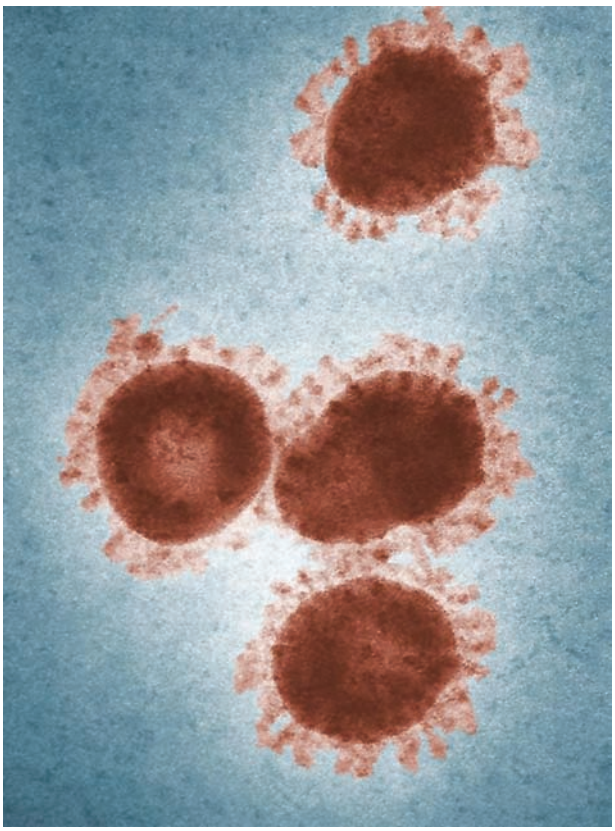
Jordan, Kuwait, Oman, Qatar, Saudi Arabia, United Arab Emirates, and Yemen, as well as Lebanon, Iran, Tunisia, and Egypt. Cases in Europe, Asia, and the United States have been travel-related, occurring in people who were infected in the Middle East. In 2013, MERS cases exported to France and the United Kingdom resulted in limited human-to-human transmission. The World Health Organization (WHO) reported in October 2014 that the number of cases was decreasing, with only sporadic new infections and small clusters in healthcare settings, although WHO warned that there could be an upsurge in the spring. There has been "no evidence for sustained human-to-human transmission in communities."

Description

Coronaviruses are named for the crown-like spikes on the viral surface. There are many different CoVs that cause a wide range of illnesses. Many CoVs infect animals, especially bats, and MERS-CoV most closely resembles other CoVs found in bats. Far fewer



A transmission electron micrograph of infectious bronchitis virus (IBV), which a kind of coronavirus. *(Dr. Fred Murphy/ Sylvia Whitfield/Centers for Disease Control and Prevention (CDC))*

CoVs infect humans, most often causing mild to moderate upper respiratory infections such as the **common cold**. However, CoVs also cause serious illnesses, such as **severe acute respiratory syndrome (SARS)**. Like the **SARS** virus, MERS-CoV can cause **respiratory failure** and other organ dysfunction. However, MERS-CoV differs from any other coronaviruses known to infect people. The majority of identified MERS cases have been characterized by severe illness, including **pneumonia**, kidney failure, and death.

Origins

MERS-CoV was first isolated in June 2012, by virologist Ron Fouchier and colleagues at the Erasmus Medical Center in Rotterdam, the Netherlands, from a sample sent by an Egyptian physician working in Jeddah, Saudi Arabia. MERS first came to public attention in September 2012, with an announcement by the Egyptian physician. Samples from an April 2012 disease outbreak in Jordan were subsequently tested and revealed that two nurses had died of MERS. The first evidence of MERS-CoV human-to-human transmission occurred within a family in Riyadh, Saudi Arabia.

As of late 2014, small and large clusters of MERS cases had been reported. A cluster was defined as two or more cases of otherwise unexplained acute respiratory infections from a single setting—such as a workplace, home, or hospital—that were serious enough to require admission to an intensive care unit. However, the connections between cases in the larger MERS clusters had not been clarified.

Public health concerns

In May 2013, Dr. Margaret Chan, director-general of WHO, called MERS-CoV her "greatest concern." The global **public health** alarm over MERS stemmed, in part, from its similarity to SARS. SARS first appeared in China in late 2002, reached Hong Kong in 2003, and then was spread rapidly by travelers to cities around the world. A mere handful of travelers transmitted the virus to large numbers of people, turning a rare disease into a global outbreak that killed almost 1,000—a mortality rate of 11%—before disappearing in 2004.

MERS-CoV is distantly related to the SARS virus. However, whereas the SARS virus is readily transmittable between people, MERS-CoV does not appear to be as easily transmitted. Nevertheless in May 2013, 13 new cases of MERS occurred among dialysis patients in a Saudi hospital. This raised the level of concern, because SARS had spread from hospitals into the community, and mortality from MERS appears to be much higher than from SARS. Furthermore, MERS-CoV replicates faster in the laboratory than the SARS virus, more readily penetrates lung cells, and inhibits immune-response proteins such as anti-viral interferons.

Risk factors

It appears that people with pre-existing medical conditions ("comorbidities") may be at greater risk for infection or more severe illness. As of 2014, these conditions included diabetes, cancer, and chronic lung, heart, and kidney diseases. People with weakened immune systems are also at greater risk for infection and more severe disease.

Causes and symptoms

Causes

MERS-CoV appears to be a zoonotic infection that originated in animals. MERS-CoV strains that match human strains have been isolated from camels

WWW.BOOKBAZ.IR

in Qatar, Oman, Saudi Arabia, and Egypt. The virus has also been found in a bat in Saudi Arabia. Camels across Africa and the Middle East have tested positive for antibodies to MERS-CoV, indicating that they had been previously infected with MERS-CoV or a closely related virus. As of 2014, no other animals had tested positive. This suggests that contact with camels or consumption of camel meat or milk may be the source of human infection.

Although MERS-CoV has spread from patients to others in the home or healthcare setting, no ongoing spread of the virus in the community has been observed. Thus, the route and mode of transmission and the types of exposure that result in infection remain unknown. For example, it is not known whether MERS-CoV can be transmitted through the air by coughing or sneezing (respiratory transmission) or via contaminated surfaces or objects. Saudi scientists have reported finding gene fragments of the virus in the air of a barn with an infected camel. Although person-to-person transmission appears limited, at least in comparison with many other viruses that cause human disease, it is not known whether MERS-CoV might evolve the capacity for easier transmission and sustained spread in human populations. As of late 2014, there were increasing reports of healthcare-associated infections, in particular in facilities where infection prevention and control measures were inadequate. There also have been reports of infections in which no potential source can be identified.

Symptoms

The clinical course and disease spectrum of MERS remained somewhat unclear as of 2014. The incubation period—the time between exposure to the virus and appearance of symptoms—appears to be between two and 14 days. Typical symptoms are **fever**, **cough**, and **shortness of breath**. Pneumonia and gastrointestinal symptoms, including **diarrhea**, nausea, and **vomiting**, are common. Some patients suffer organ failure, especially kidney failure, or **septic shock**. However, other people develop only cold-like symptoms or no symptoms at all, and infection is only discovered during follow-ups of MERS patient contacts.

Diagnosis

Examination

A **physical examination** can confirm that a patient in acute respiratory distress has pneumonia. A personal and medical history may reveal possible exposure to MERS-CoV. A laboratory test is required to confirm a MERS diagnosis.

Tests

WHO guidelines call for testing all patients who reside in or have traveled to the Middle East and subsequently developed severe acute respiratory illness, as well as immunocompromised patients who have other symptoms such as diarrhea. Patients who had close contact with a confirmed MERS case within the past ten days or who come from a community in which a MERS cluster has been identified should also be tested.

Several laboratory tests use polymerase chain reaction (PCR) to rapidly identify genetic sequences (RNA in CoVs) that are unique to MERS-CoV. If possible, the specimens for testing are obtained from the patient's respiratory tract by a procedure called bronchoalveolar lavage. Sputum can also be tested. The test quickly identifies active MERS-CoV infection.

Serology testing of a blood samples identifies antibodies to MERS-CoV to determine whether a person had been infected previously and developed an immune response. Serology for MERS-CoV involves three tests:

- a screening test called an enzyme-linked immunosorbent assay (ELISA)
- a confirming test called an immunofluorescent assay
- a slower, more definitive confirmation with a neutralizing antibody test

Procedures

Other diagnostic procedures may be performed. For example, lung x rays may reveal the severity of the illness.

Treatment

There is no specific treatment or antiviral therapy for MERS. The patient is isolated to prevent transmission of the virus, and treatment is directed at the symptoms. Respiratory failure requires mechanical ventilation and support in an intensive care unit. Some patients have been treated experimentally with **antiviral drugs** such interferon and ribavirin. However, general supportive care, including support of vital organ function, can be very effective for preventing MERS deaths.

KEY TERMS

Antibodies—Specific proteins produced by the immune system in response to specific foreign proteins or particles such as viruses.

Coronavirus (CoV)—A large family of viruses, a few of which cause human respiratory illnesses, including MERS, SARS, and the common cold.

Ebola—A severe—often fatal—viral disease that can be transmitted to humans from other mammals and spreads rapidly through communities; the cause of a major 2014 epidemic in West Africa.

Emergent disease—An infectious disease that appears in a population for the first time, rapidly increases in incidence or geographic range, becomes more virulent or treatment-resistant, or re-emerges after a long period of control or presumed elimination.

Gain-of-function (GOF)—Research aimed at making viruses that are easier to transmit or cause more serious disease, in order to recognize such strains if they emerge and design better treatments and vaccines.

Interferons—A group of small antiviral proteins that are produced by the immune system and synthesized as medications.

MERS-CoV—The coronavirus that causes Middle East respiratory syndrome.

Pandemic—An infectious disease occurring over a large geographical area or affecting a high proportion of a population.

Pathogen—A causative agent of disease, such as a bacteria, virus, or parasite.

Pneumonia—A lung disease characterized by inflammation, fever, chills, cough, and difficulty breathing; usually caused by a viral and bacterial infection.

Polymerase chain reaction (PCR)—A technique that can rapidly identify genetic material that is present in only very small quantities, such as viral RNA.

Septic shock—A life-threatening response to systemic (body-wide) infection, characterized by low blood pressure, reduced circulation, and organ dysfunction or failure.

Serology—The immunological properties of blood sera.

Severe acute respiratory syndrome (SARS)—A serious infectious disease caused by a coronavirus that was the first emergent disease of the twenty-first century, arising from transmission events between animals and humans in Chinese markets.

Zoonotic—Diseases that can be transmitted from animals to humans under natural conditions.

Prognosis

As of 2014, approximately 27% of reported MERS cases resulted in death. However, this prognosis applies only to patients with severe illness, since most mild cases of MERS presumably go undetected or unreported. Severe illnesses and deaths from MERS have occurred in older patients or those with weakened immune systems or other health problems such as diabetes, cancer, or chronic lung disease. People with mild symptoms recover fully.

Prevention

In addition to the usual prevention and control measures, healthcare facilities caring for suspected or confirmed MERS patients must take extensive precautions to prevent spread of the virus to other patients, healthcare workers, and visitors. WHO conducts ongoing MERS surveillance and requires notification of any new cases, as well as patients' potential sources of exposure and the clinical course of the disease. Identifying the sources of exposure and modes of transmission will help halt the spread of MERS-CoV.

General measures for preventing respiratory infections include:

- avoiding close contact or sharing cups or eating utensils with anyone showing symptoms such as coughing or sneezing
- frequent and thorough hand washing with soap and water or an alcohol-based hand sanitizer for 20 seconds and helping young children do the same
- avoiding raw or undercooked animal products, including milk and meat, unwashed fruits and vegetables, and any drinks prepared with non-sterilized water
- coughing or sneezing into one's sleeve, elbow, or a tissue or wearing a mask
- immediately discarding used tissues in a closed bin

WWW.BOOKBAZ.IR

- avoiding touching one's eyes, nose, and mouth with unwashed hands
- frequently cleaning and disinfecting surfaces such as doorknobs and toys

People should practice good hygiene around animals, including hand washing before and after touching them. Contact with sick animals should be avoided. As of 2014, it was unclear whether MERS-CoV causes illness in camels. Camel farm and slaughterhouse workers should take special precautions, including face protection and protective clothing and avoiding exposing family members to their work shoes, clothing, or other potentially contaminated items. Sick animals should never be slaughtered for food. Camel meat and milk should be cooked, pasteurized, or otherwise heat-treated.

Public health role and response

Emergent diseases such as MERS are on the increase. One study found that between 1940 and 2004 an average of 5.3 emergent diseases appeared each year. There are many reasons for this increase, including population growth, deforestation, harvesting of bush meat, large live-animal markets, factory farming, and overuse of **antibiotics**. With air travel and globalization, emergent diseases can spread around the globe in days.

At the same time, global disease surveillance has improved dramatically. Gene-sequencing technologies enable the rapid identification and tracking of pathogens. Daily reports of disease outbreaks are instantly available to scientists worldwide. In the aftermath of SARS, WHO regulations have forced countries to acknowledge disease outbreaks that they previously tried to hide. As a result, emergent diseases are recognized much earlier, and countermeasures, including testing and vaccines, can be developed. Disease surveillance saves many lives, but it also means that emergent diseases must be addressed, even when they are likely to disappear quickly without becoming pandemic or even a serious problem.

In 2014, the **Ebola** epidemic in West Africa overshadowed concerns about MERS, which seemed unlikely to rise to the level of a global health threat. Nevertheless, WHO was warning vulnerable countries, particularly African countries, about a possible seasonal spread of MERS during the first half of 2015. A WHO Emergency Committee also called for improved awareness and surveillance of MERS during the annual Muslim pilgrimage to Saudi Arabia. However, WHO has not advised point-of-entry screening or any travel or trade restrictions.

Research

The complexity of coronaviruses makes vaccine development very difficult, so scientists have searched for an animal model in which to study the disease. In 2014, researchers announced that MERS-CoV causes disease in marmosets, a New World monkey, that is similar to the disease in humans—replicating rapidly, spreading widely through the lungs, and causing life-threatening pneumonia. Furthermore, marmosets and humans have identical amino acids in a critical region of the receptor that MERS-CoV uses to invade cells. The use of a marmoset model could greatly improve efforts to develop drugs and vaccines to fight the disease.

In October 2014, U.S. president Barack Obama announced a moratorium on all federal funding for gain-of-function (GOF) research that could make MERS-CoV or **influenza** or SARS viruses more easily transmissible or deadly. All researchers working on GOF studies with these viruses were asked to voluntarily pause their work until potential risks and benefits could be reassessed. Many scientists, including those working on animal models of MERS, have objected strenuously to the moratorium, since it could delay discoveries that would help stop the spread of MERS-CoV.

Mifeprex *see* **Mifepristone**

Mifepristone

Definition

Mifepristone, mifeprex, RU 486, is a drug used to produce medical abortion within 49 days of the last menstrual period.

Purpose

This medication is primarily used for ending pregnancies within 19 days after the last menstrual period.

Description

Mifepristone blocks progesterone, the hormone necessary for maintaining **pregnancy**, causing the uterus to shed its lining and producing menstrual-like bleeding.

Three doctor or clinic visits are required for medical termination of pregnancy. Following a medical history, **physical examination**, and confirmation of pregnancy, 600 mg of mifepristone, three 200 mg tablets, are given as a single dose. Two days later, on day three, if termination of pregnancy cannot be confirmed, 400 mcg of misoprostol, two 200 mcg tablets, are given at one time. Additional medication, like ibuprofen, may be needed to relieve abdominal **pain** and cramping. On day 14, if termination cannot be confirmed, **dilatation and curettage** or suction evacuation of the uterine cavity is done, usually under local **anesthesia**. Depending on the amount of vaginal bleeding, a **hemoglobin test** may be needed.

Contraindications to medical termination of pregnancy

- Women who are more than seven weeks pregnant, 49 days since their last menstrual period
- Women who have an IUD, intrauterine device, for contraception
- Women who take long-term corticosteroids or have chronic adrenal failure
- Women with bleeding disorders or who take blood thinning medications like warfarin or aspirin
- Women with suspected ectopic pregnancy
- Women who do not have adequate access to emergency medical services
- Women who cannot or will not adhere to the three visit protocol for medical termination of pregnancy

Aftercare

There may be heavy bleeding and abdominal cramping when early pregnancies are interrupted with mifepristone and misoprostol.

Until vaginal bleeding has essentially stopped, sexual intercourse increases the risk of infection.

It may take days or weeks for women to stabilize their hormonal balances after medical abortion. Some women experience mood swings, **anxiety**, the blues or even depression. Though these symptoms subside over time, counseling or support groups may be helpful.

WWW.BOOKBAZ.IR

KEY TERMS

Dilatation and curettage (D and C)—A surgical procedure where the cervix is dilated and an instrument is introduced to scrape tissue from the walls of the uterus to complete termination of pregnancy.

Misprostol—A drug used in combination with mifepristone to cause uterine contractions that expel the contents of the uterus.

Complications of medical abortion

Uterine infection, with **fever** and abdominal pain and tenderness, is the most serious complication of medical abortion.

Anemia from heavy or prolonged vaginal bleeding can be a serious complication.

Other common side effects include: **fatigue**, headaches, **dizziness**, anxiety, nausea, **vomiting**, **diarrhea**, and low-back pain.

Normal results

Most women feel better within two weeks. Bleeding and spotting usually stop within 16 days, but may last up to a month.

Abnormal results

In some cases, mifepristone does not completely terminate pregnancy. When that happens, surgical termination like dilatation and curettage (D and C) or suction of the uterine cavity is required. Five to eight percent of women taking mifepristone require a surgical termination of pregnancy, according to the FDA. During a D and C, usually done under local anesthesia at a hospital or clinic, the cervix is dilated and an instrument is used to scrape residual tissue away from the walls of the uterus. This generally stops heavy bleeding.

Migraine headache

Definition

Migraine is a common primary **headache** characterized by a collection of debilitating neurological symptoms, especially severe throbbing **pain** on one or both sides of the head, lasting for several hours or more.

Demographics

Migraine is considered the most disabling neurological disease worldwide. More than 37 million Americans are believed to have migraine headaches, with almost one in four households having a migraine sufferer. Approximately 18% of women and 6% of men experience at least one migraine attack per year. About 2% of the population have chronic migraine headaches, occurring at least 15 days every month.

Migraines are most common between the ages of 15 and 55, although half of all people with migraines had their first attack before the age of 12, and migraine has been reported in babies as young as 18 months. An estimated 10% of school-age children have migraines. Migraines are rare after age 60. Prior to **puberty**, migraine is more common in boys than in girls; however, with adolescence the influence of the female hormone estrogen causes both the incidence of migraine and its severity to increase in females: Three times more adult women than men are affected. Menstrual migraine—beginning up to two days before the onset of menstruation and continuing for up to three days after onset—affects 10–14% of American women, although most such women also have migraines at other times of the month.

Description

Migraine is a syndrome—a collection of symptoms—that usually includes an intense vascular headache, meaning that the blood vessels in the tissues surrounding the head dilate and cause pain. The term *migraine* is derived from the Greek word *hemikrania*, meaning "half the head," because a classic migraine headache affects only one side of the head. However, approximately one-third of migraine sufferers have bilateral headaches.

Most people with migraine have one or two attacks per month, although a large number of people have migraines on a near-daily basis. Status migrainosus is a severe migraine that can last 72 hours or longer

and may require hospitalization. Menstrual migraines are usually more severe and more difficult to control than other types. Migraine is often associated with conditions such as depression, **anxiety**, **stroke**, **irritable bowel syndrome**, **epilepsy**, or **hypertension**. More than 90% of people are unable to work or function normally during an attack:

- 80% experience abnormal sensitivity to light and noise
- 75% have nausea and vomiting
- 30% require bed rest
- 25% missed at least one day of work due to migraine in the previous three months

There are different types of migraine, and migraine may actually represent several distinct diseases with similar symptoms. However, migraine is generally classified as one of two types: migraine without aura (MWOA) or common migraine and migraine with aura (MWA) or classic migraine, accounting for 20–30% of migraine headaches. The aura of MWA precedes or accompanies the headache pain and may include visual or other sensory disturbances, **hallucinations**, partial obstruction of the visual field, numbness or tingling in the limbs, or a feeling of heaviness. Symptoms are often most prominent on one side of the head or body and may begin as early as 72 hours before the onset of pain. Migraine auras are believed to have inspired famous works of art and literature, such as those of Hildegard of Bingen in the twelfth century and Lewis Carroll's *Alice in Wonderland*. People with MWA do not usually experience an aura with every migraine attack, and it is common to be diagnosed with both MWOA and MWA or with migraine and tension-type headaches.

Risk factors

Migraine is a genetic disease, and 70–80% of sufferers have a family history of migraine. There is some evidence that **obesity** is a risk factor for episodic migraine headaches. **Motion sickness** in children may indicate a predisposition to migraine.

Causes and symptoms

Causes

The precise causes of migraine headaches are not known, although some types of migraine have been linked to specific genetic markers. Migraine starts deep within the brain, with electrical impulses spreading to other regions of the brain. Transient changes in the activity of specific nerve cells are responsible for symptoms such as visual disturbances, **dizziness**, numbness, or tingling. Brain chemicals called neuropeptides are thought to cause blood vessel dilation and increased blood flow. Other neuropeptides increase the leakiness of the vessels, allowing fluid to leak out and promote tissue inflammation and swelling. The headache pain is caused by the spread of the excitation and inflammation to nerves connected to the trigeminal nerve, which releases chemicals that cause swelling of blood vessels on the surface of the brain, which send pain signals to the brainstem.

Triggers

A wide variety of physiological effects, foods, drugs, environmental cues, and events can trigger migraines in different people. Estrogen binding to receptors in the brain is involved in the development of migraines in many women, which may be why females often develop migraine at puberty as estrogen levels rise. Frequent, more severe attacks are often associated with fluctuations in estrogen levels. **Menopause** can also trigger migraines. Other common migraine triggers are:

- stress
- lack of sleep
- sleep changes or disturbances, including oversleeping
- prolonged overexertion or uncomfortable postures
- missing or delaying a meal
- hunger or fasting
- odors, smoke, perfume
- environmental chemicals
- bright or fluorescent lights
- strong glare or flashing lights
- sunlight
- TV and movie viewing
- excessive noise
- weather changes
- dental infections, liver problems, or various other medical conditions

Common food triggers are:

- foods that contain tyramine, including aged cheese, soy products, ripe fruit, and some processed meats
- foods containing tannins, such as tea, red apples, pears, and other fruits
- citrus fruits
- dairy products
- fermented or pickled foods

WWW.BOOKBAZ.IR

- nuts
- freshly baked yeast products
- eggs
- onions
- chocolate
- alcohol, especially red wine
- caffeine and caffeine withdrawal
- processed foods, especially those containing nitrites, sulfites, or monosodium glutamate (MSG)
- foods with extremely high sugar content
- artificial sweeteners

Paradoxically, daily or near-daily use of medications designed to prevent or relieve migraines can trigger migraines. Medication overuse of both over-the-counter and prescription drugs is believed to be a common contributor to the progression from episodic to chronic migraine. Other drugs that may trigger migraine headaches are:

- oral contraceptives
- estrogen replacement therapy
- theophylline
- teserpine
- nifedipine
- indomethicin
- cimetidine
- overuse of decongestants
- analgesic overuse
- benzodiazepine withdrawal

Symptoms

Migraines commonly develop in distinct stages:

- The prodrome (early sign) is a warning of an imminent migraine, beginning hours or even days before the aura and/or headache in 30–40% of migraine sufferers. Symptoms may include food cravings, constipation or diarrhea, mood changes such as irritability or depression, muscle or neck stiffness, fatigue, increased urination, or yawning. MWOA may be preceded by elevations in mood or energy level.
- The aura phase of MWA begins 20–60 minutes before the headache and commonly lasts 15–30 minutes. Symptoms vary greatly. Visual disturbances include wavy lines, flashing or shimmering lights, jagged arcs of white or colored light, dots, and blind spots. Other symptoms can include visual and olfactory hallucinations, numbness or tingling in the face, hand, or arms, dizziness, difficulty speaking, ringing in the ear, weakness or heaviness on one side of the body, and sensitivity to light, smells, and noises. Occasionally, auras occur without a subsequent headache.
- The headache phase is typically throbbing pain around the eye or temple but can also be pain in the face, sinus, jaw, or neck. It can switch from one side of the head to the other. The headache often occurs early in the morning, awakening the individual. It usually lasts from one to 72 hours. Other symptoms include nausea, sensitivity to light, odor, and sound, diarrhea or constipation, neck pain, nasal congestion or a runny nose, depression, severe anxiety, hot flashes, dizziness, vertigo, confusion, dehydration, vomiting, excessive perspiration and chills, blurred vision, or intolerance of food or odors. Physical activity worsens the pain.
- The postdrome or post-headache phase leaves the sufferer exhausted. The skull often remains very tender. Cerebral blood flow remains abnormal for up to 24 hours, and it usually takes hours or even days to fully recover. Symptoms can include depression or euphoria, poor concentration, or confusion. The postdrome can follow the prodrome and/or the aura without the headache phase.

Symptoms in children and adolescents may differ from those in adults. The headache is often less severe in comparison to the nausea, **vomiting**, abdominal pain, or dizziness.

Diagnosis

Examination

Diagnosis is commonly established on the basis of headache characteristics, migraine-related symptoms, and a family history of migraines. It is estimated that less than half of migraine headaches are correctly diagnosed. They are often misdiagnosed as a tension-type or sinus headache, and diagnosis in children can be particularly difficult. However, there exist specific criteria for diagnosing different types of MWA and MWOA.

Tests

There are no tests for confirming a migraine diagnosis.

Procedures

Procedures for ruling out other causes of symptoms include:

- computerized tomography (CT) scans that use computer-directed x rays of the brain to rule out tumors, infections, or other medical conditions
- magnetic resonance imaging (MRI) that uses radio waves and a powerful magnet to produce detailed views of the brain and its blood vessels for diagnosing tumors, strokes, aneurysms, and other brain abnormalities
- a spinal tap—withdrawal of a sample of cerebrospinal fluid for laboratory analysis—to diagnose diseases such as meningitis

Treatment

Traditional

There are more than 100 drugs, surgical treatments, and devices for migraine. Treatment most often relies on identifying and avoiding triggers, medications for prevention and acute symptoms, and various complementary therapies. In the past, it was thought that migraine pain was caused by the dilation and constriction of blood vessels in the brain, and this was the primary treatment target. However, it was recognized that migraine is genetically determined and involves nerve pathways and brain chemicals.

Drugs

The U.S. Food and Drug Administration (FDA) has approved over-the-counter Excedrin Migraine—a combination of **aspirin**, **acetaminophen**, and caffeine—and two ibuprofen products—Advil Migraine and Motrin Migraine Pain—for treating migraine headache pain. Although other prescription **nonsteroidal anti-inflammatory drugs** (NSAIDs) may be effective for some migraines, high doses may be required, and gastrointestinal side effects can limit their use.

More severe or unresponsive attacks may be treated with ergotamine or dihydroergotamine (DHE), often in combination with **caffeine**, sumatriptan, beta-blockers or **calcium** channel-blockers, antiseizure drugs, antidepressants such as **selective serotonin reuptake inhibitors** (SSRIs), meperidine, or metoclopramide. Some of these drugs are available as nasal sprays, intramuscular injections, or rectal suppositories when vomiting prevents taking medication by mouth. A battery-powered sumatriptan patch was approved by the FDA in 2013. Sumatriptan and other triptans (zolmitriptan, rizatriptan, naratriptan, almotriptan, eletriptan, and frovatriptan) are serotonin receptor (5-HT) agonists that narrow blood vessels. They should not be taken by people with **vascular disease** because they cause coronary artery narrowing. Otherwise these drugs are considered safe. However, they are most effective if taken early in an attack, when pain is mild and before skin sensitivity increases. Continued use of almost any headache drug can lead to "rebound headache," marked by frequent or chronic headaches, especially in the early morning. Therefore, it is important to use the minimum dose required to treat symptoms.

If abortive therapy is ineffective or headaches are very severe, narcotic painkillers may be necessary. Butorphanol, a synthetic opioid, or phenothiazines may be effective. Status migraine lasting more than 24 hours may require anti-inflammatory **corticosteroids**.

Treatment of migraine presents special problems in the elderly. The presence of other diseases or conditions may prevent the use of some medications, and older patients are more likely to experience adverse side effects. Acetaminophen is considered the safest medication for symptomatic treatment of migraine in the elderly.

Alternatives

Complementary treatments—especially **biofeedback**, relaxation techniques, **acupuncture**, and exercise—can be useful, especially for preventing migraines. Migraine headaches are one of the most common reasons for consulting naturopathic practitioners.

Naturopaths typically treat migraine with a combination of nutritional therapy and mind/body techniques. Biofeedback training uses special equipment that monitors physical tension, teaching the patient to control stress-related physical processes. Once learned, people can often stop an attack or reduce its severity without the monitoring equipment. Biofeedback training can be especially effective for children, who learn new methods quickly and have not yet become entrenched in a pattern of chronic pain.

Clinicians also teach self-hypnosis exercises that enable patients to control blood vessel swelling and muscle contraction. Autogenic training is a form of self-hypnosis developed in Germany in the 1930s that has been shown in several studies to relieve migraine pain. Such exercises should be practiced daily.

A 2013 study found that cognitive behavioral therapy, including training in coping with pain, was particularly effective for reducing the incidence of migraines and migraine-related disabilities and managing chronic migraines in children and adolescents. Other alternative treatments include:

WWW.BOOKBAZ.IR

- acupressure on the Gates of Consciousness (GB 20) points
- aromatherapy with essential oil of rosemary
- hydrotherapy or contrast showers—a short hot shower followed by a longer cold shower to halt an oncoming migraine
- a hot enema for temporary relief
- relaxation techniques, including meditation, yoga, visualization, breathing exercises, or progressive muscular relaxation to halt the progression of a migraine
- transcutaneous electrical nerve stimulation (TENS)

In 2013, the FDA approved a transcranial magnetic stimulator (TMS) for treating MWA pain. The device is held against the back of the head. A button releases a pulse of magnetic energy the stimulates the occipital cortex of the brain to reduce or eliminate migraine pain.

Clinical studies have indicated supplementation with vitamin B2 (riboflavin), 5-hydroxytryptophan (5-HTP), or melatonin can reduce the severity of migraines. Magnesium and calcium help maintain healthy blood vessels. Pantothenic acid may also be helpful.

Some herbs are used for relieving migraines:

- valerian (*Valeriana officinalis*)
- passionflower (*Passiflora incarnata*)
- feverfew (*Chrysanthemum parthenium*)
- ginger
- ginkgo (*Ginkgo biloba*)
- goldenseal (*Hydrastis canadensis*)
- hawthorn (*Crataegus oxyacantha*)
- linden
- wood betony (*Stachys officinalis*)
- skullcap (*Scutellaria lateriflora*)
- cramp bark (*Viburnum opulus*)

Home remedies

At the onset of symptoms, the person should seek out a quiet, dark room and attempt to sleep. Placing a cold, damp cloth or a cold pack on the forehead may help. A headband tied tightly around the head may provide relief.

Proper rest and diet are very important for migraine sufferers, and lifestyle changes and other non-drug treatments can help avoid attacks. A diary of foods, events, behaviors, or other factors can help identify and avoid triggers. **Food allergies** or intolerances are often associated with migraine headaches, and their identification and elimination can decrease the frequency of migraines or eliminate them altogether. Migraine sufferers should avoid nicotine and **exercise** regularly. People with migraines are typically less physically active than others and may avoid exercise out of concern that it will trigger or worsen an attack. Migraine sufferers should increase the length and intensity of exercise routines slowly and avoid any exercise that aggravates migraines. Low-impact exercise that minimizes pounding, such as stationary biking or use of elliptical equipment, is recommended. Increasing treadmill incline rather than speed also minimizes pounding movements. The neck should be protected during stretching and weight-bearing exercise. It is important to drink plenty of water, because **dehydration** is a very common migraine trigger.

Prognosis

Most people can control their migraines through identification and avoidance of triggers, effective drug combinations, and complementary therapies. Migraines usually wane in intensity by age 60. Postmenopausal women may experience fewer migraines due to lower estrogen levels.

Prevention

Identifying and avoiding triggers is the best prevention for migraines, along with **stress** management, including relaxation techniques, biofeedback, and regular aerobic exercise. Women who have identified estrogen as a trigger may need to avoid estrogen-containing medications or modify their dosage. Regular meal times and not skipping meals, regular sleeping hours and avoidance of oversleeping, reduced use of caffeine and pain-relievers, and restricting physical exertion, especially in the heat, are other preventive measures.

Medication may be able to abort migraine headaches during the prodrome or aura phase. Various drugs taken on a daily basis are used to reduce the incidence of attacks and pain intensity and improve the response to acute medications. As of 2013, there were four FDA-approved drugs for migraine prevention: propranolol, timolol, topiramite, and divalproex **sodium**. These drugs were considered first-line therapy for migraine prevention. The antidepressant amitriptyline may also be effective. These medications require adequate doses for a sufficient length of time to evaluate their effectiveness in an individual. Dose titration may be necessary to reduce adverse effects. A natural preparation made from butterbur root (*Petasites hybridus*) has been sold in Germany since the 1970s as a migraine preventive under the trade name

KEY TERMS

Aura—Visual and other sensory disturbances that can precede the onset of a migraine headache.

Autogenic training—A form of self-hypnosis developed in Germany that appears to be beneficial for migraine sufferers.

Estrogen—Any of several naturally occurring or synthetic steroid hormones that promote the growth and maintenance of the female reproductive system.

Migraine with aura (MWA)—Migraine headache that is preceded by an aura.

Migraine without aura (MWOA)—Migraine headache that is not preceded by an aura.

Nonsteroidal anti-inflammatory drugs (NSAIDs)—Over-the-counter and prescription medications for reducing pain and inflammation, including aspirin, ibuprofen, naproxen, and many others.

Postdrome—The post-headache phase of a migraine in which cerebral blood flow remains abnormal.

Prodrome—Symptoms that precede either the aura or the headache phase of a migraine.

Selective serotonin reuptake inhibitor (SSRI)—A class of antidepressants that increases levels of the neurotransmitter serotonin in the brain by preventing its reuptake by nerve cell endings.

Serotonin—A neurotransmitter in the brain and blood; low levels are associated with various disorders including migraines and depression.

Transcranial magnetic stimulator (TMS)—A device for treating migraine headaches by stimulating the brain with magnetic energy.

Transcutaneous electrical nerve stimulation (TENS)—A migraine treatment in which a mild electrical current is passed through electrodes on the skin to stimulate nerves and block pain signals.

Trigeminal nerves—The fifth and largest pair of cranial nerves; mixed motor-sensory nerves that emerge from the side of the pons in the brainstem.

Triptans—A class of drugs that bind to serotonin receptors and mimic the action of serotonin; believed to treat migraine headaches by constricting cranial blood vessels, inhibiting inflammatory neuropeptides, and blocking the transmission of pain signals.

Tyramine—A phenolic amine derived from the amino acid tryptophan and found in various foods and beverages, such as cheese and red wine, which can trigger migraines.

Petadolex. Petadolex has been available in the United States since 1998 and has passed several clinical safety and post-marketing surveillance trials.

In early 2014, the FDA approved the first headband to prevent migraine headaches from occurring. The head called Cefaly uses electrodes above the eyes to stimulate the trigeminal nerve that is central to the development of a migraine headache.
